#### Abstract

Understanding the structure of attractors is fundamental in nonautonomous stability and bifurcation theory. By means of clarifying theorems and carefully designed examples we highlight the potential complexity of attractors for nonautonomous differential equations that are as close to autonomous equations as possible. We introduce and study bounded uniform attractors and repellors for nonautonomous scalar differential equations, in particular for asymptotically autonomous, polynomial, and periodic equations. Our results suggest that uniformly attracting or repelling solutions are the true analogues of attracting or repelling fixed points of autonomous systems. We provide sharp conditions for the autonomous structure to break up and give way to a bewildering diversity of nonautonomous bifurcations.

## 1. Introduction

From the plethora of tools for analysing the asymptotic behaviour of autonomous differential equations

$$
\begin{equation*}
\dot{x}=F(x), \tag{1}
\end{equation*}
$$

many have been extended to nonautonomous equations

$$
\begin{equation*}
\dot{x}=f(t, x), \tag{1}
\end{equation*}
$$

e.g. spectral theory $[38,42]$, invariant manifold theory [3,48], or the Hartman-Grobman theorem [4,34,43]. As an important common feature, all these generalisations assume uniformity in time $t \in \mathbb{R}$ of some sort or other, for instance via exponential dichotomies of a linearisation or via Lipschitz conditions independent of $t$. Imposing uniformity

[^0]conditions is reasonable if a priori knowledge on the time dependence of $f$ is available, e.g. if $f$ is periodic, almost periodic or automorphic in $t$ [41], but it may become questionable if the dependence on $t$ is more complex. For a comprehensive study of bifurcation scenarios for instance an analysis of more general time dependencies is indispensable.

The recent past has seen numerous attempts to extend bifurcation theory to nonautonomous differential equations [ $9,13,16-19,22,25,27,28,36]$. While classical bifurcation theory for dynamical systems (1) describes the change of stability and the creation, annihilation and break up of equilibria, periodic, heteroclinic and homoclinic orbits etc., it is, in the nonautonomous situation of $(1)_{t}$, not at all obvious the bifurcations of which objects one should study; equilibria and periodic orbits for instance are not generic for $(1)_{t}$ if $f$ depends aperiodically on $t$. One natural approach is to study the transition of attractors [25]. For example, a classical (supercritical) two-dimensional Hopf bifurcation could be understood as a transition from a singleton attractor (consisting of an asymptotically stable equilibrium) to a more complex attractor (bounded by an attractive periodic orbit and containing in its interior a repelling equilibrium). While a classical attractor for (1) is simply a compact invariant set which attracts a neighbourhood, there exist several nonequivalent definitions for nonautonomous attractors, e.g. forward and pullback attractors [6] describing, respectively, the future and the past of $(1)_{t}$. Consequently, in order to better understand nonautonomous bifurcation scenarios one has to analyse the structure and transition of these attractors whenever Eq. (1) depends on a parameter. Typically, attractors depend merely upper semi-continuously on parameters; the dependence is continuous only if the attraction is uniform w.r.t. the parameter [29]. Clearly, establishing the existence of some (globally) attracting object can only be the first step of an in-depth analysis. Looking inside an attractor, however, usually is much more demanding. To the best of our knowledge no systematic study of internal attractor bifurcations for nonautonomous equations exists so far. Bifurcation results available often rely on the fact that attracting solutions can be computed and analysed explicitly $[25,27]$ or employ somewhat technical or restrictive assumptions on the system under consideration, as for instance in the formidable balance of Taylor coefficients utilised in [28].

The purpose of this article is to lay the foundations for internal attractor bifurcation studies. In the simplest possible setting we illustrate by means of clarifying theorems and carefully designed examples the potential structural complexity of attractors for equations which are as close to autonomous differential equations as possible. We study attraction and repulsion properties of individual solutions (i.e., the natural analogues of autonomous equilibria) of nonautonomous scalar differential equation (1) $)_{t}$. In Section 2 we propose the definition of a bounded uniform attractor which incorporates two of the most popular mechanisms of attraction, namely forward and pullback attraction. In the autonomous situation of (1), all notions of attraction coincide. In general, a uniform attractor for $(1)_{t}$ is substantially more than just a forward attractor that is also pullback attracting (see Examples 5 and 12); as far as we know, this important point has not been clarified in the literature before. In Section 3 we study in detail the properties of uniform attractors and repellors for nonautonomous equation (1) $)_{t}$ where we maintain various autonomous features by focusing on equations that are, respectively, asymptotically autonomous (Section 3.1), polynomial in $x$ (Section 3.2), and periodic in $t$ (Section 3.3). While all notions of attraction coincide for scalar periodic equations (Theorem 23), in general the classes of forward, pullback, and uniform attractors are all different, the latter being strictly smaller than the intersection of the two former.

From Section 3.2 onward, we pay special attention to uniform attractors and repellors of Eq. (1) $)_{t}$ that are polynomial in $x$,

$$
\begin{equation*}
\dot{x}=\varepsilon\left(a_{0}(t)+a_{1}(t) x+\cdots+a_{d}(t) x^{d}\right) \tag{2}
\end{equation*}
$$

with $\varepsilon>0$. In the autonomous case, that is, for $a_{0}, a_{1}, \ldots, a_{d}$ not depending on $t$, the total number of uniformly attracting and repelling solutions of (2) is, quite trivially, bounded by $d$. The latter bound turns out to be correct as well if either (2) is asymptotically autonomous, if $\varepsilon>0$ is sufficiently small, or if $d \leq 3$, where in the case $d=3$ additional assumptions have to be imposed on $a_{3}$ (see Theorem 21 for details). Quite different arguments are required to deal with each situation. Moreover, none of the assumptions mentioned can be omitted. We demonstrate this by means of a series of results which unite and profoundly extend ideas scattered throughout the literature. To give but one example, even for periodic coefficients $a_{i}$ Eq. (2) may have any (finite) number of uniform attractors if $d \geq 3-$ provided that $\varepsilon$ is not too small (Theorem 28). Thus a non-trivial bifurcation problem emerges for (2) upon variation of $\varepsilon$. Our results strongly suggest that the notion of uniform attractors and repellors will be useful in tackling problems of
this kind. Accordingly, we conclude this article by indicating several fundamental questions that arise naturally from the results presented.

## 2. Bounded uniform attractors and repellors

In this article we consider nonautonomous scalar differential equations

$$
\begin{equation*}
\dot{x}=f(t, x), \tag{3}
\end{equation*}
$$

where $f: \mathbb{R}^{2} \rightarrow \mathbb{R}$ as well as $\frac{\partial}{\partial x} f$ is continuous in $(t, x)$. Moreover, we assume throughout that $\sup _{\mathbb{R} \times K}|f|<\infty$ for every compact set $K \subset \mathbb{R}$. Given $\left(t_{0}, x_{0}\right) \in \mathbb{R}^{2}$ the initial value problem consisting of (3) together with $x\left(t_{0}\right)=x_{0}$ has a unique solution $t \mapsto \varphi\left(t ; t_{0}, x_{0}\right)$ defined on some (possibly bounded) maximal open interval containing $t_{0}$. Although solutions of (3) may (and often will) become unbounded in finite time we are particularly interested in bounded solutions. A bounded solution $\mu: \mathbb{R} \rightarrow \mathbb{R}$ of (3) can attract or repel neighbouring solutions in different ways.

Example 1. Let $\psi$ denote the bounded $C^{1}$ function

$$
\psi: t \mapsto \frac{t|t|}{1+t^{2}} \quad(t \in \mathbb{R})
$$

which, together with its primitive

$$
\Psi: t \mapsto \int_{0}^{t} \psi(s) \mathrm{d} s=|t|-|\arctan t| \quad(t \in \mathbb{R})
$$

will be used several times throughout this article as an auxiliary function. With this, consider the equation

$$
\begin{equation*}
\dot{x}=\cos t+\psi(t) \sin t-\psi(t) x \tag{4}
\end{equation*}
$$

which, for all $\left(t_{0}, x_{0}\right) \in \mathbb{R}^{2}$, has the solution

$$
\varphi\left(t ; t_{0}, x_{0}\right)=\mathrm{e}^{\Psi\left(t_{0}\right)-\Psi(t)}\left(x_{0}-\sin t_{0}\right)+\sin t
$$

Obviously, all solutions of (4) exist for all time, every solution is bounded, and

$$
\begin{equation*}
\lim _{t \rightarrow \infty}\left|\varphi\left(t ; t_{0}, x_{0}\right)-\sin t\right|=0, \quad \forall\left(t_{0}, x_{0}\right) \in \mathbb{R}^{2} \tag{5}
\end{equation*}
$$

Thus the bounded solution $\mu_{1}: t \mapsto \sin t$ of (4) attracts all solutions in forward time (see Fig. 1). It is an example of a (global) forward attractor.

Example 2. Analogously, for the equation

$$
\begin{equation*}
\dot{x}=\cos t-\psi(t) \sin t+\psi(t) x, \tag{6}
\end{equation*}
$$

we find, for all $\left(t_{0}, x_{0}\right) \in \mathbb{R}^{2}$,

$$
\varphi\left(t ; t_{0}, x_{0}\right)=\mathrm{e}^{\Psi(t)-\Psi\left(t_{0}\right)}\left(x_{0}-\sin t_{0}\right)+\sin t
$$

Now $\mu_{2}: t \mapsto \sin t$ is the only bounded solution of (6). Evidently, it is not attracting in the sense of the previous example (see Fig. 1). However, $\mu_{2}$ attracts all solutions in the sense that, at any given time $t$, solutions satisfying an initial condition at time $t_{0}$ much smaller than $t$ are close to $\mu_{2}(t)$. Formally

$$
\begin{equation*}
\lim _{t_{0} \rightarrow-\infty}\left|\varphi\left(t ; t_{0}, x_{0}\right)-\sin t\right|=0, \quad \forall t \in \mathbb{R}, x_{0} \in \mathbb{R} . \tag{7}
\end{equation*}
$$

Thus $\mu_{2}$ is an example of a (global) pullback attractor.
It is obvious that $\mu_{1}$ is not pullback attracting for (4) whereas $\mu_{2}$ is not forward attracting for (6). Evidently, this discrepancy is due to the highly non-uniform convergence in (5) and (7). Observations like these naturally motivate parts (iii) and (iv) of Definition 3. This definition may look slightly unfamiliar to the reader proficient in the theory of nonautonomous attractors, as developed e.g. in [7,8,23,24]. The subsequent Remark 4 explicates why Definition 3 nevertheless is the most appropriate for our purposes.

Fig. 1. Forward (left, see Example 1) and pullback attraction (Example 2) are different concepts.
Definition 3. Let $\mu: \mathbb{R} \rightarrow \mathbb{R}$ be a bounded solution of (3) and $\left(x_{0, \sigma}\right)_{\sigma \in \mathbb{R}}$ a family of real numbers. The solution $\mu$ is called
(i) a forward attractor if there exists $\delta>0$ such that, for every $t_{0} \in \mathbb{R}$,

$$
\lim _{\tau \rightarrow \infty}\left|\varphi\left(t_{0}+\tau ; t_{0}, x_{0, t_{0}}\right)-\mu\left(t_{0}+\tau\right)\right|=0,
$$

whenever $\sup _{\sigma \in \mathbb{R}}\left|x_{0, \sigma}-\mu(\sigma)\right|<\delta$;
(ii) a pullback attractor if there exists $\delta>0$ such that, for every $t \in \mathbb{R}$,

$$
\lim _{\sigma \rightarrow-\infty}\left|\varphi\left(t ; \sigma, x_{0, \sigma}\right)-\mu(t)\right|=0,
$$

whenever $\sup _{\sigma \in \mathbb{R}}\left|x_{0, \sigma}-\mu(\sigma)\right|<\delta$;
(iii) a uniform attractor if there exists $\delta>0$ such that

$$
\lim _{\tau \rightarrow \infty}\left\|\varphi\left(\cdot+\tau ; \cdot, x_{0,}\right)-\mu(\cdot+\tau)\right\|_{\infty}=\lim _{\tau \rightarrow \infty} \sup _{\sigma \in \mathbb{R}}\left|\varphi\left(\sigma+\tau ; \sigma, x_{0, \sigma}\right)-\mu(\sigma+\tau)\right|=0,
$$

provided that $\sup _{\sigma \in \mathbb{R}}\left|x_{0, \sigma}-\mu(\sigma)\right|<\delta$;
(iv) a uniform repellor if there exists $\delta>0$ such that

$$
\lim _{\tau \rightarrow \infty}\left\|\varphi\left(\cdot-\tau ; \cdot, x_{0, \cdot}\right)-\mu(\cdot-\tau)\right\|_{\infty}=\lim _{\tau \rightarrow \infty} \sup _{\sigma \in \mathbb{R}}\left|\varphi\left(\sigma-\tau ; \sigma, x_{0, \sigma}\right)-\mu(\sigma-\tau)\right|=0,
$$

provided that $\sup _{\sigma \in \mathbb{R}}\left|x_{0, \sigma}-\mu(\sigma)\right|<\delta$.
We call $\mu$ a global forward, pullback, uniform attractor or uniform repellor if the respective property above holds for every $\delta>0$.

Remark 4. (i) Forward and pullback attractors are usually defined much more generally as families (parametrised by $t$ ) of non-empty compact sets which are attractive and invariant in some sense or other. Attraction typically occurs only within an attracting universe [23], that is, a parametrised family of non-empty bounded sets satisfying further consistency and regularity conditions. Since we are interested in attraction phenomena on the finest scale we focus on attractors and repellors which are solutions of (3), i.e., every $t$-fibre is a singleton. Thus Definition 3 really is a tailor-made specialisation of more general concepts. Also note that the solutions of (3) are ordered, that is, $\varphi\left(t ; t_{0}, x_{0}\right)<\varphi\left(t ; t_{0}, y_{0}\right)$ for all $t$ whenever $x_{0}<y_{0}$. Consequently, the condition $\sup _{\sigma \in \mathbb{R}}\left|x_{0, \sigma}-\mu(\sigma)\right|<\delta$ in Definition 3 corresponds to an attractive universe consisting of all nonautonomous sets $\left(D_{\sigma}\right)_{\sigma \in \mathbb{R}}$ with $\sup _{x \in D_{\sigma}}|x-\mu(\sigma)|<\delta$ for all $\sigma \in \mathbb{R}$ or, equivalently, the attracting universe generated by the set-valued map $\sigma \mapsto] \mu(\sigma)-\delta, \mu(\sigma)+\delta[$. For a global attractor or repellor $\mu$, therefore, the corresponding universe would comprise, at any $\sigma \in \mathbb{R}$, all bounded sets containing $\mu(\sigma)$.
(ii) In principle, one could allow the solution $\mu$ in Definition 3 to be unbounded. If so, (3) may have more attractors than is desirable. For a trivial example take $f(t, x) \equiv-x$ in (3); every solution is then a uniform attractor, but only the equilibrium $\mu=0$ is bounded. Also, from a practical point of view (cf. [26]), it may be hard to distinguish actual divergence from convergence towards an unbounded "attractor".
(iii) The notions of uniform attractor and repellor exhibit a natural duality. Such natural dual counterparts exist neither for forward nor for pullback attractors [6,21,25,27].

Example 5. Trivially, every uniform attractor is both a forward and a pullback attractor. The converse is not true in general as the following example shows.

For every $a \in \mathbb{R}$ let $h_{a}$ denote the bounded continuous function

$$
h_{a}: t \mapsto 1-a-\pi \max (0, \sin \sqrt{|t|}) \quad(t \in \mathbb{R}),
$$

and consider the equation

$$
\begin{equation*}
\dot{x}=\cos t-h_{a}(t) \sin t+h_{a}(t) x, \tag{8}
\end{equation*}
$$

for which a short computation yields

$$
\begin{equation*}
\varphi\left(t ; t_{0}, x_{0}\right)=\left(x_{0}-\sin t_{0}\right) \mathrm{e}^{\int_{t_{0}}^{t} h_{a}(s) \mathrm{d} s}+\sin t \quad \forall\left(t_{0}, x_{0}\right) \in \mathbb{R}^{2} . \tag{9}
\end{equation*}
$$

Since $h_{a}$ is even, the solution $\mu: t \mapsto \sin t$ of (8) is a forward attractor if and only if it is a pullback attractor, which in turn is the case precisely if $a>0$. On the other hand, given any $\tau>0$, pick $N \in \mathbb{N}$ such that $(2 N+1)^{2} \pi^{2}+\tau<(2 N+2)^{2} \pi^{2}$, that is, $N>\frac{1}{4} \pi^{-2}\left(\tau-3 \pi^{2}\right)$. Choosing in particular $t_{0}=(2 N+1)^{2} \pi^{2}$ we immediately deduce from (9) that

$$
\sup _{\sigma \in \mathbb{R}}\left|\varphi\left(\sigma+\tau ; \sigma, x_{0, \sigma}\right)-\sin (\sigma+\tau)\right| \geq\left|x_{0}-\sin t_{0}\right| \mathrm{e}^{\tau(1-a)}
$$

Thus $\mu$ is not a uniform attractor if $a \leq 1$. For $a>1$ obviously $h_{a} \leq 1-a<0$, so

$$
\sup _{\sigma \in \mathbb{R}}\left|\varphi\left(\sigma+\tau ; \sigma, x_{0, \sigma}\right)-\sin (\sigma+\tau)\right| \leq \mathrm{e}^{\tau(1-a)} \sup _{\sigma \in \mathbb{R}}\left|x_{0, \sigma}-\sin \sigma\right| \rightarrow 0 \quad \text { as } \tau \rightarrow \infty,
$$

which shows that $\mu$ is a global uniform attractor if and only if $a>1$.
Example 6. Two bounded solutions $\mu_{1}, \mu_{2}$ of (3) may be separated in the sense that their distance $\inf _{t \in \mathbb{R}} \mid \mu_{1}(t)-$ $\mu_{2}(t) \mid$ is positive. Any uniform attractor is necessarily separated from any uniform repellor (cf. the proof of Theorem 19). It is, however, worth noting that $\lim _{t \rightarrow \infty}\left|\mu_{1}(t)-\mu_{2}(t)\right|=0$ for two uniform attractors $\mu_{1}, \mu_{2}$ is not ruled out by Definition 3. Concretely, consider the equation

$$
\begin{equation*}
\dot{x}=\frac{1}{2}(1-\psi(t)) x-\frac{1}{2} x^{3}, \tag{10}
\end{equation*}
$$

the solutions of which are given by

$$
\begin{equation*}
\varphi\left(t ; t_{0}, x_{0}\right)=\frac{x_{0}}{\sqrt{\mathrm{e}^{\Psi(t)-t-\Psi\left(t_{0}\right)+t_{0}}+x_{0}^{2} \int_{t_{0}}^{t} \mathrm{e}^{\Psi(t)-t-\Psi(s)+s} \mathrm{~d} s}} \quad \forall\left(t_{0}, x_{0}\right) \in \mathbb{R}^{2}, t \geq t_{0} \tag{11}
\end{equation*}
$$

Taking the limit $t_{0} \rightarrow-\infty$ in (11) yields two candidates for pullback attractors for (10), namely $\mu$ and $-\mu$, where

$$
\mu: t \mapsto \frac{1}{\sqrt{\int_{-\infty}^{t} \mathrm{e}^{\Psi(t)-t-\Psi(s)+s} \mathrm{~d} s}} \quad(t \in \mathbb{R})
$$

It is easy to check that $\mu$ and $-\mu$ are indeed bounded monotone solutions of (10) and that $\lim _{t \rightarrow \infty} \mu(t)=0$ (see Fig. 2). The introduction of a new coordinate $\xi$ via $x=\xi \mu$ transforms (10) into

$$
\dot{\xi}=\frac{1}{2} \mu(t)^{2} \xi\left(1-\xi^{2}\right),
$$

from which an equivalent form of (11),

$$
\begin{equation*}
\varphi\left(t ; t_{0}, x_{0}\right)=\mu(t) \frac{x_{0} \mathrm{e}^{\frac{1}{2} \int_{t_{0}}^{t} \mu(s)^{2} \mathrm{~d} s}}{\sqrt{\mu\left(t_{0}\right)^{2}-x_{0}^{2}+x_{0}^{2} \mathrm{e}_{t_{0}}^{t} \mu(s)^{2} \mathrm{~d} s}} \quad \forall\left(t_{0}, x_{0}\right) \in \mathbb{R}^{2}, t \geq t_{0}, \tag{12}
\end{equation*}
$$

Fig. 2. The two uniform attractors $\mu$ and $-\mu$ of (10) are not separated.
can be derived easily. The representation (12) is particularly useful for showing that $\mu$ and $-\mu$ are in fact uniform attractors of (10). Since $\lim _{t \rightarrow \infty}|\mu(t)-(-\mu(t))|=0$ these two attractors are evidently not separated.

From Theorem 13 it follows that $\lim _{t \rightarrow-\infty} \mu(t)=\sqrt{2}$. This theorem also implies that the zero solution of (10) which in Fig. 2 appears somewhat repelling is not a uniform repellor; while it is not a uniform attractor either, it is obviously a forward attractor.

Example 7. To observe an infinite number of attractors that are not separated consider

$$
\begin{equation*}
\dot{x}=-\mathrm{e}^{t}\left(1+\mathrm{e}^{t}\right)^{-1} x+\left(1+\mathrm{e}^{t}\right)^{-1} H\left(x\left(1+\mathrm{e}^{t}\right)\right), \tag{13}
\end{equation*}
$$

where $H$ denotes the $C^{\infty}$ function

$$
H(x)= \begin{cases}0 & \text { if } x=0 \\ \mathrm{e}^{-|x|^{-1}} \sin \left(x^{-1}\right) & \text { if } x \neq 0\end{cases}
$$

For every $k \in \mathbb{Z} \backslash\{0\}$ the function

$$
\mu_{k}: t \mapsto \frac{1}{k \pi}\left(1+\mathrm{e}^{t}\right)^{-1} \quad(t \in \mathbb{R})
$$

is a solution of (13). As in Example 6 it is straightforward to check that $\mu_{k}$ is a uniform attractor whenever $k$ is even. Note also that for odd $k$ the solution $\mu_{k}$, albeit somewhat repelling, is not a uniform repellor but - like every solution of (13) - a forward attractor.

The following simple fact implicitly underlies most of the subsequent arguments, and we recall it here for the reader's convenience, see e.g. [47].

Proposition 8. Let $\mu_{1}<\mu_{2}$ be two bounded solutions of (3). Then the solution of (3) with $x\left(t_{0}\right)=x_{0}$ exists for all $t \in \mathbb{R}$ whenever $\mu_{1}\left(t_{0}\right) \leq x_{0} \leq \mu_{2}\left(t_{0}\right)$.

## 3. Properties of uniform attractors

A uniform attractor resembles an attracting equilibrium in the autonomous case. We now analyse analogies and differences between the two concepts. Recall that throughout we assume $f$ in (3), and also $\frac{\partial}{\partial x} f$, to be continuous in $(t, x)$ and bounded on every stripe $\mathbb{R} \times K, K$ compact.

### 3.1. Autonomous and asymptotically autonomous differential equations

In the autonomous case, that is for $f(t, x) \equiv F(x)$ not depending on $t$, all notions of attraction coincide, and attractors are easily characterised in terms of $F$. Essentially, this is due to the invariance of (1) under time translations.

Theorem 9. Let $F$ be $C^{1}$ and $\mu: \mathbb{R} \rightarrow \mathbb{R}$ a bounded solution of $\dot{x}=F(x)$. Then the following statements are equivalent:
(i) $\mu$ is a forward attractor;
(ii) $\mu$ is a pullback attractor;
(iii) $\mu$ is a uniform attractor;
(iv) $\mu$ is constant, $\mu(t) \equiv \mu_{0}$, and $\mu_{0}$ is an isolated zero of $F$ such that $F(a)>0>F(b)$ for all $a<\mu_{0}<b$ with $b-a$ sufficiently small.

Proof. Current as well as later arguments become especially transparent by means of $\alpha$ - and $\omega$-limit sets and their nonautonomous counterparts $[15,33]$. Quite generally, therefore, for every bounded continuous function $v: \mathbb{R} \rightarrow \mathbb{R}$ we denote by $\alpha(v)$ and $\omega(v)$ the set of all backward and forward accumulation points of $\{v(t): t \in \mathbb{R}\}$, respectively, i.e.,

$$
\begin{aligned}
& \alpha(v)=\left\{x \in \mathbb{R}: \exists\left(t_{n}\right) \text { s.t. } t_{n} \rightarrow \infty, v\left(-t_{n}\right) \rightarrow x\right\} \\
& \omega(v)=\left\{x \in \mathbb{R}: \exists\left(t_{n}\right) \text { s.t. } t_{n} \rightarrow \infty, v\left(t_{n}\right) \rightarrow x\right\}
\end{aligned}
$$

It is well known (and easy to see) that $\alpha(v), \omega(v)$ are non-empty compact intervals (which may, of course, degenerate to single points).

Every solution $\mu$ of $\dot{x}=F(x)$ is monotonic, and therefore the limits $\lim _{t \rightarrow-\infty} \mu(t)=\mu_{-}$and $\lim _{t \rightarrow \infty} \mu(t)=\mu_{+}$ exist if $\mu$ is bounded. Thus $\alpha(\mu)=\left\{\mu_{-}\right\}$and $\omega(\mu)=\left\{\mu_{+}\right\}$. Clearly, $F\left(\mu_{-}\right)=F\left(\mu_{+}\right)=0$. Assume now that $\mu$ is a forward attractor. If $\mu_{-} \neq \mu_{+}$and $\delta>0$, then there exists $t_{0}$ such that $\left|\mu_{-}-\mu\left(t_{0}\right)\right|<\delta$ yet

$$
\left|\varphi\left(t_{0}+\tau ; t_{0}, \mu_{-}\right)-\mu\left(t_{0}+\tau\right)\right|=\left|\mu_{-}-\mu\left(t_{0}+\tau\right)\right| \rightarrow\left|\mu_{-}-\mu_{+}\right| \neq 0 \quad \text { as } \tau \rightarrow \infty
$$

contradicting the fact that $\mu$ is a forward attractor. Hence $\mu_{+}=\mu_{-}=\mu_{0}$, and $\mu$ is constant. Similarly, if $\mu$ is a pullback attractor then, for all $\sigma \leq t_{0}$ with $t_{0}$ sufficiently small, $\left|\mu_{-}-\mu(\sigma)\right|<\delta$ and so, choosing $x_{0, \sigma}$ equal to $\mu_{-}$ or $\mu(\sigma)$, depending on whether $\sigma \leq t_{0}$ or $\sigma>t_{0}$, we find

$$
\lim _{\sigma \rightarrow-\infty}\left|\varphi\left(t ; \sigma, x_{0, \sigma}\right)-\mu(t)\right|=\left|\mu_{-}-\mu(t)\right| \neq 0
$$

unless $\mu$ is constant. In either case therefore $\mu(t) \equiv \mu_{0}$ and $F\left(\mu_{0}\right)=0$. If there existed a strictly increasing sequence $\left(a_{n}\right)$ with $a_{n} \rightarrow \mu_{0}$ and $F\left(a_{n}\right) \leq 0$ for all $n$ then $\varphi\left(t ; t_{0}, a_{n}\right)$ would neither converge to $\mu_{0}$ as $t \rightarrow \infty$ nor as $t_{0} \rightarrow-\infty$. A completely analogous argument yields that $F(b)<0$ for all $b$ larger than but sufficiently close to $\mu_{0}$. Overall, this shows that (i) and (ii), and hence also (iii), imply (iv).

Conversely, assume that $F\left(\mu_{0}\right)=0$ and $F(a)>0>F(b)$ for all $a, b$ with $a_{0} \leq a<\mu_{0}<b \leq b_{0}$ and appropriate $a_{0}<\mu_{0}<b_{0}$. For every $x_{0} \in\left[a_{0}, b_{0}\right]$ the solution $\varphi\left(t ; t_{0}, x_{0}\right)$ exists for all $t \geq t_{0}$, and, with $\delta=\min \left(b_{0}-\mu_{0}, \mu_{0}-a_{0}\right)>0$,

$$
\begin{aligned}
\sup _{\sigma \in \mathbb{R}}\left|\varphi\left(\sigma+\tau ; \sigma, x_{0, \sigma}\right)-\mu_{0}\right| & =\sup _{\sigma \in \mathbb{R}}\left|\varphi\left(\tau ; 0, x_{0, \sigma}\right)-\mu_{0}\right| \\
& \leq \max \left(\left|\varphi\left(\tau ; 0, a_{0}\right)-\mu_{0}\right|,\left|\varphi\left(\tau ; 0, b_{0}\right)-\mu_{0}\right|\right) \rightarrow 0 \quad \text { as } \tau \rightarrow \infty
\end{aligned}
$$

provided that $\sup _{\sigma \in \mathbb{R}}\left|x_{0, \sigma}-\mu(\sigma)\right|<\delta$. Thus $\mu=\mu_{0}$ is a uniform attractor.
Corollary 10. Let $F$ be $C^{1}$ and $\mu: \mathbb{R} \rightarrow \mathbb{R}$ a bounded solution of $\dot{x}=F(x)$. Then $\mu$ is a uniform repellor if and only if $\mu(t) \equiv \mu_{0}$ and $\mu_{0}$ is an isolated zero of $F$ such that $F(a)<0<F(b)$ for all $a<\mu_{0}<b$ with $b-a$ sufficiently small.
Proof. We only have to observe that $\mu$ is a uniform repellor if and only if $t \mapsto \mu(-t)$ is a uniform attractor for the equation $\dot{x}=-F(x)$.

Recall that (3) is termed asymptotically autonomous if for two (necessarily continuous) functions $f_{-}, f_{+}: \mathbb{R} \rightarrow \mathbb{R}$

$$
\lim _{t \rightarrow-\infty} f(t, x)=f_{-}(x), \quad \lim _{t \rightarrow \infty} f(t, x)=f_{+}(x)
$$

holds locally uniformly in $x$. (See e.g. [33,44,45] for information and references on the extensive theory of asymptotically autonomous systems; note that solutions of the limiting equations $\dot{x}=f_{-}(x)$ and $\dot{x}=f_{+}(x)$ may fail to be unique if $f_{-}, f_{+}$are not Lipschitz continuous.) In some respects, asymptotically autonomous systems resemble autonomous ones, but there are also various counterexamples to the intuition that the asymptotic behaviour of (3) and its limit equations $\dot{x}=f_{-}(x), \dot{x}=f_{+}(x)$ are necessarily the same [45]. The latter point is emphasised by the
following example which shows that the equivalence of all notions of attraction, as established by Theorem 9 for the autonomous case, does not even extend to asymptotically autonomous systems.

Example 11. Let $a_{0}, a_{1}$ denote the bounded $C^{1}$ functions

$$
a_{0}(t)=\mathrm{e}^{-\Psi(t)} \quad \text { and } \quad a_{1}(t)=-1-\psi(t) \quad(t \in \mathbb{R}),
$$

respectively, with the functions $\psi$ and $\Psi$ introduced in Example 1, and consider the asymptotically autonomous equation

$$
\begin{equation*}
\dot{x}=a_{0}(t)+a_{1}(t) x \tag{14}
\end{equation*}
$$

for which $f_{-}(x) \equiv 0$ and $f_{+}(x)=-2 x$. An elementary computation confirms that

$$
\mu: t \mapsto \mathrm{e}^{-\Psi(t)}=a_{0}(t) \quad(t \in \mathbb{R})
$$

is a global forward but not a pullback attractor for (14).
Similarly, choosing $C^{1}$ functions $a_{0}, a_{1}$ as

$$
a_{0}(t)=\mathrm{e}^{\Psi(t)-t^{2}}(1-2 t) \quad \text { and } \quad a_{1}(t)=-1+\psi(t) \quad(t \in \mathbb{R})
$$

yields another asymptotically autonomous equation (14) with $f_{-}(x)=-2 x, f_{+}(x) \equiv 0$. In this case, the bounded solution

$$
\mu: t \mapsto \mathrm{e}^{\Psi(t)-t^{2}} \quad(t \in \mathbb{R})
$$

fails to be forward attracting but nevertheless is a global pullback attractor.
Example 12. In the setting of the previous example, let

$$
a_{0}(t)=\mathrm{e}^{-t^{2}}(1-2 t), \quad a_{1}(t)=|t|^{-\frac{1}{4}} \min (0, \sin \sqrt{|t|}) \quad(t \in \mathbb{R})
$$

Again, (14) is asymptotically autonomous with $f_{+}(x)=f_{-}(x) \equiv 0$. Define $A_{1}(t)=\int_{0}^{t} a_{1}(s) \mathrm{d} s, t \in \mathbb{R}$. Then the $C^{1}$ function

$$
\mu: t \mapsto \int_{-\infty}^{t} a_{0}(s) \mathrm{e}^{A_{1}(t)-A_{1}(s)} \mathrm{d} s \quad(t \in \mathbb{R})
$$

is a bounded solution of (14) with $\lim _{|t| \rightarrow \infty} \mu(t)=0$. It is easy to check that $\mu$ is both a global forward and pullback attractor. An argument similar to the one in Example 5 shows that $\mu$ is not a uniform attractor, essentially because $A_{1}$ contains arbitrarily long constant sections.

Thus for asymptotically autonomous equations all concepts discussed so far are different. Nevertheless, for uniform attractors Theorem 9 in a sense extends to such equations.

Theorem 13. Assume (3) is asymptotically autonomous, and let $\mu: \mathbb{R} \rightarrow \mathbb{R}$ be a uniform attractor. Then the limits

$$
\lim _{t \rightarrow-\infty} \mu(t)=\mu_{-}, \quad \lim _{t \rightarrow \infty} \mu(t)=\mu_{+}
$$

exist and satisfy $f_{-}\left(\mu_{-}\right)=f_{+}\left(\mu_{+}\right)=0$. Moreover, for all $a<\mu_{+}<b$ with $b-a$ sufficiently small, $f_{+}(a) \geq 0 \geq f_{+}(b)$. Similarly, $f_{-}(c) \geq 0 \geq f_{-}(d)$ for all $c<\mu_{-}<d$ with $d-c$ sufficiently small. Furthermore, $f_{-}$and $f_{+}$do not vanish identically on any neighbourhood of $\mu_{-}$and $\mu_{+}$, respectively.

Proof. We only prove the assertions concerning $f_{+}$and $\mu_{+}$because the arguments for backward time are completely analogous. Assume that $\mu$ is a uniform attractor and let $\omega(\mu)=\left[\omega_{1}, \omega_{2}\right]$. Since $\lim _{\inf }^{t \rightarrow \infty} ⿵ 冂(t)$ would be smaller or larger than $\omega_{1}$ if $f_{+}\left(\omega_{1}\right)$ were, respectively, negative or positive, we must have $f_{+}\left(\omega_{1}\right)=0$, and in fact $f_{+}(x)=0$ for every $x \in \omega(\mu)$.

Assume now that $\omega_{1}<\omega_{2}$ and define $a(t)=\sup _{x \in \omega(\mu)}|f(t, x)|, t \in \mathbb{R}$, as well as $c=\frac{2}{3} \omega_{1}+\frac{1}{3} \omega_{2}, d=\frac{1}{3} \omega_{1}+\frac{2}{3} \omega_{2}$. We can find a strictly increasing sequence $\left(s_{n}\right)$ with $s_{n} \rightarrow \infty$ such that, for all $n \in \mathbb{N}, \mu\left(\left[s_{n}, s_{n}+n\right]\right) \subset[c, d]$ and $\sup _{t \geq s_{n}} a(t)<\frac{1}{6}\left(\omega_{2}-\omega_{1}\right) / n$, but also $\int_{S_{n}}^{s_{n}+n} a(s) \mathrm{d} s \rightarrow 0$ as $n \rightarrow \infty$. Given $\delta>0$, let $\delta^{\prime}=\min \left(\delta, \frac{1}{6}\left(\omega_{2}-\omega_{1}\right)\right)$
and assume that $\left|x_{0}-\mu\left(s_{n}\right)\right|<\delta^{\prime}$. Then both $\mu(t)$ and $\varphi\left(t ; s_{n}, x_{0}\right)$ are contained in $\omega(\mu)$ for all $s_{n} \leq t \leq s_{n}+n$. Assuming without loss of generality that $\int_{s_{n}}^{s_{n}+n} a(s) \mathrm{d} s<\frac{1}{8} \delta^{\prime}$ for all $n$ and that $\mu\left(s_{n}\right)>x_{0}$, we deduce from the trivial estimate

$$
\mu(t)-\varphi\left(t ; s_{n}, x_{0}\right) \geq \mu\left(s_{n}\right)-x_{0}-2 \int_{s_{n}}^{t} a(s) \mathrm{d} s \quad \forall t \in\left[s_{n}, s_{n}+n\right],
$$

that $\mu(t)-\varphi\left(t ; s_{n}, x_{0}\right) \geq\left|\mu\left(s_{n}\right)-x_{0}\right|-\frac{1}{4} \delta^{\prime}$ for all $t \in\left[s_{n}, s_{n}+n\right]$. Let $x_{0, \sigma}=\mu\left(s_{n}\right)-\frac{1}{2} \delta^{\prime}$ if $\sigma=s_{n}$ for some $n$, and $x_{0, \sigma}=\mu(\sigma)$ otherwise. Then $\mu(t)-\varphi\left(t ; s_{n}, x_{0, s_{n}}\right) \geq \frac{1}{4} \delta^{\prime}$ for all $t \in\left[s_{n}, s_{n}+n\right]$ and therefore

$$
\limsup _{\tau \rightarrow \infty} \sup _{\sigma \in \mathbb{R}}\left|\varphi\left(\sigma+\tau ; \sigma, x_{0, \sigma}\right)-\mu(\sigma+\tau)\right| \geq \frac{1}{4} \delta^{\prime}
$$

while $\left\|x_{0,-}-\mu(\cdot)\right\|_{\infty}<\delta^{\prime}$. This contradicts the fact that $\mu$ is a uniform attractor. Consequently, $\omega_{1}=\omega_{2}=\mu_{+}$.
The preceding arguments also show that $f_{+}$cannot vanish identically on any neighbourhood of $\mu_{+}$. Finally, if $f_{+}\left(a_{n}\right)<0$ for all $n \in \mathbb{N}$ and some increasing sequence $\left(a_{n}\right)$ with $a_{n} \rightarrow \mu_{+}$then, for $t_{0}$ sufficiently large, $\varphi\left(t ; t_{0}, a_{n}\right)$ does not converge to $\mu_{+}$as $t \rightarrow \infty$, which clearly contradicts the fact that $\mu$ is an attractor.

Corollary 14. If $\mu$ is a uniform repellor of the asymptotically autonomous equation $\dot{x}=f(t, x)$ then the limits $\lim _{t \rightarrow-\infty} \mu(t)=\mu_{-}, \lim _{t \rightarrow \infty} \mu(t)=\mu_{+}$exist and satisfy $f_{-}\left(\mu_{-}\right)=f_{+}\left(\mu_{+}\right)=0$. For all $a<\mu_{+}<b$ with $b-a$ sufficiently small, $f_{+}(a) \leq 0 \leq f_{+}(b)$, and for all $c<\mu_{-}<d$ with $d-c$ sufficiently small, $f_{-}(c) \leq 0 \leq f_{-}(d)$. Also, $f_{-}$and $f_{+}$do not vanish identically on any neighbourhood of $\mu_{-}$and $\mu_{+}$, respectively.

Example 15. Theorem 13 and Corollary 14 should be seen as extensions of, respectively, Theorem 9 and Corollary 10 to asymptotically autonomous equations and their uniform attractors. An analogous statement for forward or pullback attractors is false. For example, the equation

$$
\dot{x}=\frac{4 \sqrt{2} t^{2}|t|}{1+t^{4}} \cos \left(\log \left(1+t^{4}\right)\right)-\frac{4 t^{2}|t|}{1+t^{4}} x
$$

is asymptotically autonomous, with $f_{+}=f_{-}=0$, and has

$$
\mu: t \mapsto \sin \left(\frac{\pi}{4}+\operatorname{sign} t \cdot \log \left(1+t^{4}\right)\right) \quad(t \in \mathbb{R})
$$

as a global forward and pullback attractor. (Here, as usual, $\operatorname{sign} t$ equals 1,0 or -1 , depending on whether $t \in \mathbb{R}$ is positive, zero or negative.) It follows from Theorem 13 that $\mu$ is not a uniform attractor; this can also be confirmed by a short direct computation.

Example 16. Unlike Theorem 9 for the autonomous case, Theorem 13 does not assert that $\mu_{+}$is an isolated zero of $f_{+}$. In general, this cannot be expected as the following example shows.

Define $f: \mathbb{R}^{2} \rightarrow \mathbb{R}$ as

$$
f(t, x)= \begin{cases}0 & \text { if } x=0 \\ -x \mathrm{e}^{-|x|^{-1}}\left(\left(1+\mathrm{e}^{-t^{2}} \operatorname{sign} x\right) \sin ^{2}\left(x^{-1}\right)+\mathrm{e}^{-t^{2}}\right)^{\frac{1}{4}} & \text { if } x \neq 0\end{cases}
$$

so that $f$ is $C^{\infty}$ in $t$ and $x$, and $f(t, x) \rightarrow f_{ \pm}(x)$ locally uniformly as $|t| \rightarrow \infty$, where

$$
f_{ \pm}(x)= \begin{cases}0 & \text { if } x=0 \\ -x \mathrm{e}^{-|x|^{-1}}\left|\sin \left(x^{-1}\right)\right|^{\frac{1}{2}} & \text { if } x \neq 0\end{cases}
$$

Obviously, $\mu=0$ is a solution of $\dot{x}=f(t, x)$. As before let $t \mapsto \varphi\left(t ; t_{0}, x_{0}\right)$ denote the (unique) solution of the latter equation with $x\left(t_{0}\right)=x_{0}$. Furthermore, let $w$ be any solution of the autonomous initial value problem

$$
\begin{equation*}
\dot{w}=f_{ \pm}(w), \quad w(0)=x_{0} . \tag{15}
\end{equation*}
$$

As $\left(f_{+}(x)-f(t, x)\right) \operatorname{sign} x \geq 0$ for all $(t, x) \in \mathbb{R}^{2}$ it follows from elementary differential inequality considerations [47, p. 95] that $\left(w\left(t-t_{0}\right)-\varphi\left(t ; t_{0}, x_{0}\right)\right) \operatorname{sign} x_{0} \geq 0$ for all $t \geq t_{0}$. Choosing in particular $w$ as
the minimal solution of (15) if $x_{0}>0$, and as the maximal solution if $x_{0}<0$, we see that $\mu$ is indeed a uniform attractor, but clearly $\mu_{+}=0$ is not an isolated zero of $f_{ \pm}$.

Example 16 is somewhat pathological in that (15) does not have a unique solution. An additional regularity assumption on the limiting functions simplifies the situation.

Theorem 17. If, under the assumptions of Theorem 13, the functions $f_{-}$and $f_{+}$are $C^{1}$ then $\mu_{-}$and $\mu_{+}$are isolated zeros of $f_{-}$and $f_{+}$, respectively.
Proof. Again it is enough to verify the assertion for forward time. Assume that $f_{+}\left(\mu_{n}\right)=0$ for all $n \in \mathbb{N}$ and some monotone sequence ( $\mu_{n}$ ) with $\mu_{n} \rightarrow \mu_{+}$; without loss of generality let ( $\mu_{n}$ ) be strictly decreasing. We are going to show that this assumption is incompatible with $\mu$ being a uniform attractor - provided that $f_{+}$is $C^{1}$.

If $f_{+}^{\prime}\left(\mu_{n}\right) \neq 0$ for infinitely many $n$ then there exist points $x>\mu_{+}$with $x-\mu_{+}>0$ arbitrarily small such that $f(t, x)$ is positive for all sufficiently large $t$. This, however, is impossible because $\mu$ is an attractor. Without loss of generality we can thus assume that $f_{+}^{\prime}\left(\mu_{n}\right)=0$ for all $n \in \mathbb{N}$. Given $\delta>0$, choose $N \in \mathbb{N}$ such that $\left|\mu(t)-\mu_{N}\right|<\delta$ for all $t \geq N$. For every $k \in \mathbb{N}$ there exists $0<\varepsilon_{k}<\frac{1}{3}\left(\mu_{N}-\mu_{+}\right)$such that $\left|f_{+}^{\prime}(x)\right|<\frac{1}{2 k}$ whenever $\left|x-\mu_{N}\right|<\varepsilon_{k}$. Consequently, we can find a strictly increasing sequence $\left(T_{k}\right)_{k \in \mathbb{N}}$ with $T_{1}>N$ such that $|f(t, x)|<\frac{\varepsilon_{k}}{k}$ for all $t \geq T_{k}$ and all $x \in\left[\mu_{N}-\varepsilon_{k}, \mu_{N}+\varepsilon_{k}\right]$, and also $\mu(t)<\frac{2}{3} \mu_{+}+\frac{1}{3} \mu_{N}$ whenever $t \geq T_{1}$. It follows that $\varphi\left(t ; T_{k}, \mu_{N}\right)$ is an element of $\left[\mu_{N}-\varepsilon_{k}, \mu_{N}+\varepsilon_{k}\right]$ for (at least) all $t \in\left[T_{k}, T_{k}+k\right]$. Choose now $x_{0, \sigma}=\mu_{N}$ if $\sigma=T_{k}$ for some $k$, and $x_{0, \sigma}=\mu(\sigma)$ otherwise. Clearly, $\sup _{\sigma \in \mathbb{R}}\left|x_{0, \sigma}-\mu(\sigma)\right|<\delta$. Observing that

$$
\begin{aligned}
\sup _{\sigma \in \mathbb{R}}\left|\varphi\left(\sigma+\tau ; \sigma, x_{0, \sigma}\right)-\mu(\sigma+\tau)\right| & \geq\left|\varphi\left(T_{k}+\tau ; T_{k}, \mu_{N}\right)-\mu\left(T_{k}+\tau\right)\right| \\
& \geq\left|\mu_{N}-\mu\left(T_{k}+\tau\right)\right|-\left|\mu_{N}-\varphi\left(T_{k}+\tau ; T_{k}, \mu_{N}\right)\right| \\
& >\frac{2}{3}\left(\mu_{N}-\mu_{+}\right)-\frac{1}{3}\left(\mu_{N}-\mu_{+}\right)=\frac{1}{3}\left(\mu_{N}-\mu_{+}\right)>0
\end{aligned}
$$

for all $\tau \in[0, k]$, we deduce that $\left\|\varphi\left(\cdot+\tau ; \cdot, x_{0, .}\right)-\mu(\cdot+\tau)\right\|_{\infty} \nrightarrow 0$ as $\tau \rightarrow \infty$ and that therefore $\mu$ cannot be a uniform attractor. This contradiction completes the proof.

Remark 18. (i) Theorem 17 applies in particular if $\frac{\partial}{\partial x} f$ converges locally uniformly as $t \rightarrow-\infty$ and $t \rightarrow \infty$, respectively. In this case, and unlike in Example 16, long-term regularity prevails over spatial complexity (as measured by $\frac{\partial}{\partial x} f$ ). In one way or the other, most questions regarding uniform attractors touch upon a subtle balance between temporal and spatial complexity.
(ii) The function $f_{ \pm}$in Example 16 is not Lipschitz continuous. Since it guarantees the uniqueness of solutions of (15), Lipschitz continuity of $f_{-}$and $f_{+}$is often incorporated in the definition of asymptotically autonomous differential equations [33,44]. One may wonder whether Theorem 17 remains valid with $f_{-}$and $f_{+}$being merely Lipschitz continuous. No proof or counterexample is yet known to the authors.

### 3.2. Polynomial differential equations

From now on we focus on Eq. (3) with $f$ polynomial in $x$, that is, on equations

$$
\begin{equation*}
\dot{x}=a_{0}(t)+a_{1}(t) x+\cdots+a_{d}(t) x^{d} \tag{16}
\end{equation*}
$$

where $d \in \mathbb{N}_{0}$ does not depend on $t$ and $a_{0}, a_{1}, \ldots, a_{d}$ are bounded continuous functions. Motivated by the obvious bound in the autonomous case, that is for $a_{0}, a_{1}, \ldots, a_{d}$ not depending on $t$, we shall be interested in the maximal number of uniform attractors and repellors that (16) can have. Generally, the problem of counting special solutions of (16), notably periodic ones (see Section 3.3), has attracted considerable interest, not least for its connection with Hilbert's Sixteenth Problem, and has consequently been discussed under many different perspectives, see e.g. [1, 10, $20,30-32,35,40,46]$ and the many references therein.

For asymptotically autonomous equation (16) a bound on the numbers of uniform attractors and repellors follows immediately from Theorem 13 and Corollary 14.

Theorem 19. If the limits $\lim _{t \rightarrow-\infty} a_{i}(t), \lim _{t \rightarrow \infty} a_{i}(t)$ exist for every $i=0,1, \ldots, d$ then the total number of uniform attractors and repellors of (16) is at most $d$.

Proof. We shall use the following informal terminology: Two bounded solutions $\mu_{1}, \mu_{2}$ of (3) are joined at $-\infty$ and $\infty$ if, respectively, $\lim _{t \rightarrow-\infty}\left|\mu_{1}(t)-\mu_{2}(t)\right|=0$ and $\lim _{t \rightarrow \infty}\left|\mu_{1}(t)-\mu_{2}(t)\right|=0$. Two attractors can be joined at $\infty$ (recall Example 6). It is, however, impossible for two uniform attractors $\mu_{1}, \mu_{2}$ to be joined at $-\infty$ (and thus also for two uniform repellors to be joined at $\infty$ ). Indeed, if $\mu_{1}<\mu_{2}$ were joined at $-\infty$ then, for every $\delta>0$ there would exist $t_{0}<0$ such that $0<\mu_{2}(t)-\mu_{1}(t)<\delta$ for all $t \leq t_{0}$; with

$$
x_{0, \sigma}= \begin{cases}\mu_{2}(\sigma) & \text { if } \sigma \leq t_{0}, \\ \mu_{1}(\sigma) & \text { if } \sigma>t_{0},\end{cases}
$$

therefore $\sup _{\sigma \in \mathbb{R}}\left|x_{0, \sigma}-\mu_{1}(\sigma)\right|<\delta$. However, for all $\tau>-t_{0}$

$$
\left\|\varphi\left(\cdot+\tau ; \cdot, x_{0, .}\right)-\mu_{1}(\cdot+\tau)\right\|_{\infty} \geq\left|\varphi\left(0 ;-\tau, x_{0,-\tau}\right)-\mu_{1}(0)\right|=\mu_{2}(0)-\mu_{1}(0)>0,
$$

so $\left\|\varphi\left(\cdot+\tau ; \cdot, x_{0,}\right)-\mu_{1}(\cdot+\tau)\right\|_{\infty} \nrightarrow 0$ as $\tau \rightarrow 0$, which clearly contradicts the fact that $\mu_{1}$ is a uniform attractor. Completely similar reasoning shows that no uniform attractor can be joined at all to any uniform repellor.

To prove the theorem, let $\mu_{-}^{(1)}<\cdots<\mu_{-}^{\left(d_{-}\right)}$and $\mu_{+}^{(1)}<\cdots<\mu_{+}^{\left(d_{+}\right)}$denote the different zeros of $f_{-}$and $f_{+}$, respectively, where clearly $d_{-}, d_{+} \leq d$. (We can assume that neither $f_{-}$nor $f_{+}$vanishes identically as otherwise (16) would not have any uniform attractors or repellors.) Also, let $\mu_{1}<\cdots<\mu_{L}$ be a finite family of uniform attractors and repellors of (16). According to Theorem 13 there exist numbers $1 \leq k_{1} \leq \cdots \leq k_{L} \leq d_{-}$and $1 \leq l_{1} \leq \cdots \leq l_{L} \leq d_{+}$such that

$$
\lim _{t \rightarrow-\infty} \mu_{i}=\mu_{-}^{\left(k_{i}\right)}, \quad \lim _{t \rightarrow \infty} \mu_{i}=\mu_{+}^{\left(l_{i}\right)} \quad(i=1, \ldots, L)
$$

If $\mu_{i}$ is a uniform attractor then $l_{i+1} \geq l_{i}$ because solutions do not intersect over time. If $l_{i+1}=l_{i}$ then $\mu_{i+1}$ must also be an attractor, and $k_{i+1} \geq k_{i}+2$. This follows from the fact that for every solution $x$ between $\mu_{i}$ and $\mu_{i+1}$ the set $\alpha(x)$ must contain a zero of $f_{-}$between $\mu_{-}^{\left(k_{i}\right)}$ and $\mu_{-}^{\left(k_{i+1}\right)}$ that is different from both numbers. If, on the other hand, $l_{i+1}>l_{i}$ then $\mu_{i+1}$ could be an attractor or a repellor and thus $k_{i+1} \geq k_{i}+1$. In either case therefore $k_{i+1}+l_{i+1} \geq k_{i}+l_{i}+2$. Completely analogous reasoning shows that the latter inequality also holds if $\mu_{i}$ is a uniform repellor. Since clearly $k_{1}+l_{1} \geq 2$ we have $k_{i}+l_{i} \geq 2 i$ for all $i$. On the other hand, $k_{i}+l_{i} \leq d_{-}+d_{+}$for all $i$ so that $L \leq \frac{1}{2}\left(d_{-}+d_{+}\right)$. Eq. (16) can thus have at most $\left\lfloor\frac{1}{2}\left(d_{-}+d_{+}\right)\right\rfloor \leq d$ uniform attractors and repellors. (Here, as usual, $\lfloor t\rfloor$ denotes the largest integer not larger than $t \in \mathbb{R}$.)

Remark 20. (i) The bound $\left\lfloor\frac{1}{2}\left(d_{-}+d_{+}\right)\right\rfloor$provided by the proof of Theorem 19 is sharp, as can be seen for instance from Eq. (10) in Example 6 which exhibits two uniform attractors and for which $d_{-}=3, d_{+}=1$.
(ii) It should be noted that the stipulated uniformity and the polynomial structure of (16) are both indispensable in Theorem 19. Example 7 for instance presents an asymptotically autonomous $f=f(t, x)$ for which $f_{-}=H$ is not polynomial in $x$ and for which (3) has infinitely many uniform attractors. On the other hand, with $d=1$ and

$$
a_{0}(t) \equiv 0, \quad a_{1}(t)=-\psi(t) \quad(t \in \mathbb{R}),
$$

every solution of (16) is bounded and a forward attractor, while clearly none is a uniform attractor.
Without the assumption of asymptotic autonomy the situation becomes more intricate. We first extend Theorem 19 to equations for which $d$ is small.

Theorem 21. Let $d=0,1$ or 2 and $a_{0}, \ldots, a_{d}$ be bounded continuous functions. Then the total number of uniform attractors and repellors of (16) is at most $d$. This is true also for $d=3$, provided that $a_{3}$ is either non-negative or non-positive and $\int_{-\infty}^{0}\left|a_{3}(t)\right| \mathrm{d} t=\int_{0}^{\infty}\left|a_{3}(t)\right| \mathrm{d} t=\infty$.
Proof. We deal with each case separately. If $d=0$ then

$$
\frac{\mathrm{d}}{\mathrm{~d} t}\left(x_{2}-x_{1}\right)=0
$$

for any two solutions $x_{1}, x_{2}$ of (16). Hence $x_{2}-x_{1}$ is constant and no solution can attract or repel any other.
If $d=1$ then, for any three different solutions $x_{1}<x_{2}<x_{3}$ of (16),

$$
\frac{\mathrm{d}}{\mathrm{~d} t}\left(\frac{x_{2}-x_{1}}{x_{3}-x_{1}}\right)=\frac{x_{2}-x_{1}}{x_{3}-x_{1}}\left(\frac{\dot{x}_{2}-\dot{x}_{1}}{x_{2}-x_{1}}-\frac{\dot{x}_{3}-\dot{x}_{1}}{x_{3}-x_{1}}\right)=\frac{x_{2}-x_{1}}{x_{3}-x_{1}}\left(a_{1}-a_{1}\right)=0,
$$

Fig. 3. Ruling out the existence of $d+1$ uniform attractors and repellors for (16) with $d=1,2,3$.
so $\frac{x_{2}-x_{1}}{x_{3}-x_{1}}$ is constant. Assume that (16) has two uniform attractors $\mu_{1}<\mu_{2}$ that are joined at $\infty$. Then, for every solution $x$ between $\mu_{1}$ and $\mu_{2}, x=\mu_{1}+\rho\left(\mu_{2}-\mu_{1}\right)$ with some constant $0<\rho<1$. Clearly this contradicts the uniformity of $\mu_{1}$ and $\mu_{2}$ and therefore no two attractors (and similarly no two repellors) of (16) can be joined for $d=1$ (see left part of Fig. 3). If, however, $\mu_{1}<\mu_{2}$ are two bounded solutions with $\inf _{t \in \mathbb{R}}\left|\mu_{1}(t)-\mu_{2}(t)\right|>0$ then neither of them can be attracting or repelling. Overall, we conclude that (16) has at most one uniform attractor or repellor if $d=1$.

If $d \leq 3$ then, for any four different solutions $x_{1}<x_{2}<x_{3}<x_{4}$ of (16),

$$
\begin{equation*}
\frac{\mathrm{d}}{\mathrm{~d} t}\left(\frac{x_{3}-x_{1}}{x_{2}-x_{1}} \frac{x_{4}-x_{2}}{x_{4}-x_{3}}\right)=\frac{x_{3}-x_{1}}{x_{2}-x_{1}} \frac{x_{4}-x_{2}}{x_{4}-x_{3}}\left(-a_{3}\right)\left(x_{4}-x_{1}\right)\left(x_{3}-x_{2}\right) \tag{17}
\end{equation*}
$$

For $d=2$, therefore, the cross ratio $C R\left(x_{1}, x_{2}, x_{3}, x_{4}\right)=\frac{x_{3}-x_{1}}{x_{2}-x_{1}} \frac{x_{4}-x_{2}}{x_{4}-x_{3}}$ is constant. As before, assume that three uniform attractors $\mu_{1}<\mu_{2}<\mu_{3}$ are joined at $\infty$. Then, for every solution $x$ between $\mu_{2}$ and $\mu_{3}$,

$$
x=(1-\rho) \mu_{1}+\rho \mu_{3} \quad \text { with } \rho=\frac{\gamma\left(\mu_{2}-\mu_{1}\right)}{\mu_{3}-\mu_{2}+\gamma\left(\mu_{2}-\mu_{1}\right)}
$$

where $\gamma$ is a positive constant. Note that $\rho$ now depends on $t$ but, as before, $0<\rho(t)<1$ for all $t \in \mathbb{R}$. From $\mu_{3}-x=(1-\rho)\left(\mu_{3}-\mu_{1}\right)$ we see that $\mu_{3}$ cannot be a uniform attractor (see middle part of Fig. 3). Thus at most two uniform attractors (or repellors) can be joined if $d=2$. If, however, $\inf _{t \in \mathbb{R}}\left|\mu_{3}(t)-\mu_{2}(t)\right|>0$ then $\sup _{t \in \mathbb{R}} \rho(t)<1$ and $\mu_{3}$ cannot possibly be uniformly attracting in either forward or backward time. Therefore, (16) has at most two uniform attractors and repellors for $d=2$.

Finally, consider the case $d=3$ and let $\mu_{1}<\mu_{2}<\mu_{3}<\mu_{4}$ be four bounded solutions of (16). Assume first that $m=\min _{i=1}^{3} \inf _{t \geq 0}\left|\mu_{i+1}(t)-\mu_{i}(t)\right|>0$, that is, no two solutions are joined at $\infty$, and let $M=$ $\max _{i=1}^{3} \sup _{t \geq 0}\left|\mu_{i+1}(t)-\mu_{i}(t)\right|$. If $a_{3} \geq 0$ then we deduce from (17), for any $t_{0} \geq 0$,

$$
C R\left(\mu_{1}, \mu_{2}, \mu_{3}, \mu_{4}\right) \leq\left. C R\left(\mu_{1}, \mu_{2}, \mu_{3}, \mu_{4}\right)\right|_{t_{0}} \mathrm{e}^{-m^{2} \int_{t_{0}}^{t} a_{3}(s) \mathrm{d} s}
$$

Thus $C R\left(\mu_{1}(t), \mu_{2}(t), \mu_{3}(t), \mu_{4}(t)\right) \rightarrow 0$ as $t \rightarrow \infty$, contradicting the obvious (lower) bound

$$
C R\left(\mu_{1}, \mu_{2}, \mu_{3}, \mu_{4}\right) \geq \frac{m^{2}}{M^{2}}>0 \quad \forall t \geq 0
$$

On the other hand, for $a_{3} \leq 0$, (17) implies

$$
C R\left(\mu_{1}, \mu_{2}, \mu_{3}, \mu_{4}\right) \geq\left. C R\left(\mu_{1}, \mu_{2}, \mu_{3}, \mu_{4}\right)\right|_{t_{0}} \mathrm{e}^{-m^{2} \int_{t_{0}}^{t} a_{3}(s) \mathrm{d} s}
$$

so $C R\left(\mu_{1}(t), \mu_{2}(t), \mu_{3}(t), \mu_{4}(t)\right) \rightarrow \infty$ as $t \rightarrow \infty$, which clearly contradicts the upper bound

$$
C R\left(\mu_{1}, \mu_{2}, \mu_{3}, \mu_{4}\right) \leq \frac{M^{2}}{m^{2}} \quad \forall t \geq 0
$$

The only conceivable configuration containing four uniform attractors and repellors that is not covered by the preceding argument and its "mirrored" version (i.e., considering $t \leq 0$ instead of $t \geq 0$ ) consists of a pair of attractors ( $\mu_{1}<\mu_{2}$, say) joined at $\infty$ and a pair of repellors ( $\mu_{3}<\mu_{4}$, say, with $\mu_{2}<\mu_{3}$ ) joined at $-\infty$ (see lower right part of Fig. 3; the configuration depicted in the upper right part of Fig. 3 for instance is ruled out by the above argument for $t \rightarrow-\infty$.). In this case, rewrite (17) in the form

$$
\frac{\mathrm{d}}{\mathrm{~d} t} C R\left(\mu_{1}, \mu_{3}, \mu_{2}, \mu_{4}\right)=C R\left(\mu_{1}, \mu_{3}, \mu_{2}, \mu_{4}\right) a_{3}\left(\mu_{4}-\mu_{1}\right)\left(\mu_{3}-\mu_{2}\right)
$$

to deduce that $t \mapsto C R\left(\mu_{1}, \mu_{3}, \mu_{2}, \mu_{4}\right)$ is monotone. For the configuration considered here, that is, for the case $\lim _{t \rightarrow \infty}\left(\mu_{2}(t)-\mu_{1}(t)\right)=\lim _{t \rightarrow-\infty}\left(\mu_{4}(t)-\mu_{3}(t)\right)=0$, we have

$$
\lim _{|t| \rightarrow \infty} C R\left(\mu_{1}, \mu_{3}, \mu_{2}, \mu_{4}\right)=0
$$

Consequently $C R\left(\mu_{1}, \mu_{3}, \mu_{2}, \mu_{4}\right)=0$, an obvious absurdity. With this it has been demonstrated that (17) cannot have four uniform attractors and repellors if $d=3$.

To the unprejudiced reader Theorem 21 must seem unsatisfactory, its statement being dictated solely by the limitations of the simple arguments used in the course of the proof. It may thus come as a surprise that Theorem 21 is in a sense best possible, as will become apparent in the next section (Theorem 28 and Corollary 29).

### 3.3. Periodic differential equations

Apart from the asymptotically autonomous case, the simplest situation occurs in (3) if $f$ is $T$-periodic in the first argument, that is, if

$$
\begin{equation*}
f(t+T, x)=f(t, x), \quad \forall(t, x) \in \mathbb{R}^{2} \tag{18}
\end{equation*}
$$

with some $T>0$. We shall see shortly that, as far as uniform attractors and repellors are concerned, even this apparently tame class of equations allows for considerable structural complexity. First, however, we recall a few simple general facts about periodic differential equations. For the latter, the complete information about all solutions of (3) is encoded in the family of local homeomorphisms $\Phi_{s}: x \mapsto \varphi(s ; 0, x), 0 \leq s \leq T$, and in particular in $\Phi_{T}$, the Poincaré map associated with (3). More formally, for all $\left(t_{0}, x_{0}\right) \in \mathbb{R}^{2}$ and $t \in \mathbb{R}$, and whenever $\varphi\left(t ; t_{0}, x_{0}\right)$ is defined,

$$
\varphi\left(t ; t_{0}, x_{0}\right)=\Phi_{s_{2}} \circ \Phi_{T}^{k} \circ \Phi_{s_{1}}^{-1}\left(x_{0}\right)
$$

where $s_{1}=t_{0}-T\left\lfloor t_{0} / T\right\rfloor, s_{2}=t-T\lfloor t / T\rfloor$, and $k=\lfloor t / T\rfloor-\left\lfloor t_{0} / T\right\rfloor$, hence $0 \leq s_{1}, s_{2}<T$ and $k \in \mathbb{Z}$. Therefore the long-term dynamics of (3) is governed by $\Phi_{T}$. For instance, $\mu$ is a $p T$-periodic solution with $p \in \mathbb{N}$ if and only if $\mu(0)$ is a fixed point of $\Phi_{T}^{p}$. Also, it is easy to see that the period of every non-constant periodic solution of (3) is a rational multiple of $T$, and in fact has to be of the form $\frac{1}{q} T$ for some $q \in \mathbb{N}$ (i.e., the solution is superharmonic) because $\Phi_{T}$ is order-preserving [14,41].

Lemma 22. Let $f$ satisfy (18) and assume that $\mu: \mathbb{R} \rightarrow \mathbb{R}$ is a (forward, pullback, or uniform) attractor or a uniform repellor of (3). Then $\mu$ is $T$-periodic.
Proof. Let $\mu$ be a bounded solution and observe that, since $\Phi_{T}$ is monotone and $\mu(k T)=\Phi_{T}^{k}(\mu(0))$ for all $k \in \mathbb{Z}$, the sequence $(\mu(k T))_{k \in \mathbb{Z}}$ is monotone and bounded. Hence the limits $\mu_{-}=\lim _{k \rightarrow-\infty} \mu(k T)$ and $\mu_{+}=\lim _{k \rightarrow \infty} \mu(k T)$ exist; moreover, $\Phi_{T}\left(\mu_{-}\right)=\mu_{-}$and $\Phi_{T}\left(\mu_{+}\right)=\mu_{+}$. Let $\nu_{-}, v_{+}$denote the $T$-periodic solutions corresponding to these two fixed points of $\Phi_{T}$, that is,

$$
v_{-}(t)=\varphi\left(t ; 0, \mu_{-}\right), \quad v_{+}(t)=\varphi\left(t ; 0, \mu_{+}\right) \quad(t \in \mathbb{R}) .
$$

From

$$
\left|\mu(t)-v_{+}(t)\right|=\left|\Phi_{t-T\left\lfloor\frac{t}{T}\right\rfloor}\left(\mu\left(T\left\lfloor\frac{t}{T}\right\rfloor\right)\right)-\Phi_{t-T\left\lfloor\frac{t}{T}\right\rfloor}\left(\mu_{+}\right)\right| \leq \sup _{0 \leq s \leq T}\left|\Phi_{s}\left(\mu\left(T\left\lfloor\frac{t}{T}\right\rfloor\right)\right)-\Phi_{s}\left(\mu_{+}\right)\right|
$$

we see that $\left|\mu(t)-v_{+}(t)\right| \rightarrow 0$ as $t \rightarrow \infty$. Analogously, $\left|\mu(t)-v_{-}(t)\right| \rightarrow 0$ as $t \rightarrow-\infty$.

Assume now that $\mu$ is a forward attractor. Since, for any $\delta>0,\left|\mu\left(t_{0}\right)-v_{-}\left(t_{0}\right)\right|<\delta$ for some sufficiently small $t_{0}$, we find

$$
0=\lim _{\tau \rightarrow \infty}\left|\varphi\left(t_{0}+\tau ; t_{0}, \mu\left(t_{0}\right)\right)-v_{-}\left(t_{0}+\tau\right)\right|=\lim _{t \rightarrow \infty}\left|\mu(t)-v_{-}(t)\right|
$$

and thus in particular $\left|\mu(k T)-v_{-}(k T)\right|=\left|\mu(k T)-\mu_{-}\right| \rightarrow 0$ as $k \rightarrow \infty$. Therefore $\mu_{+}=\mu_{-}$, and $\mu$ is $T$-periodic.
Next assume that $\mu$ is a pullback attractor. Given $\delta>0$, define $x_{0, \sigma}$ to be $\nu_{-}(\sigma)$ or $\mu(\sigma)$ depending on whether $\left|\mu(\sigma)-v_{-}(\sigma)\right|<\delta$ or not. Since, for all $t \in \mathbb{R}$,

$$
0=\lim _{\sigma \rightarrow-\infty}\left|\varphi\left(t ; \sigma, x_{0, \sigma}\right)-\mu(t)\right|=\left|\nu_{-}(t)-\mu(t)\right|,
$$

we find $\mu=\nu_{-}$, hence $\mu$ is $T$-periodic.
The remaining assertions are now obvious.
As in the autonomous case, attractors of a $T$-periodic equation can be characterised easily in terms of the associated Poincaré map $\Phi_{T}$.

Theorem 23. Assume (18) holds, and let $\mu: \mathbb{R} \rightarrow \mathbb{R}$ be a bounded solution of (3). Then the following statements are equivalent:
(i) $\mu$ is a forward attractor;
(ii) $\mu$ is a pullback attractor;
(iii) $\mu$ is a uniform attractor;
(iv) $\mu$ is $T$-periodic and $\mu(0)$ is an isolated fixed point of $\Phi_{T}$ such that $\Phi_{T}(a)-a>0>\Phi_{T}(b)-b$ for all $a<\mu(0)<b$ with $b-a$ sufficiently small.

Proof. Let $\mu$ be a forward or pullback attractor. By Lemma 22, $\mu$ is $T$-periodic and hence $\mu(0)$ is a fixed point of $\Phi_{T}$. If there existed a strictly increasing sequence $\left(a_{n}\right)$ with $a_{n} \rightarrow \mu(0)$ and $\Phi_{T}\left(a_{n}\right) \leq a_{n}$ for all $n$ then $\Phi_{T}^{k}\left(a_{n}\right) \nRightarrow \mu(0)$ as $k \rightarrow \infty$, so that $\mu$ could not be forward attracting. Setting $x_{0, \sigma}=a_{n}$ if $\sigma / T$ is an integer, and $x_{0, \sigma}=\mu(\sigma)$ otherwise, we would have

$$
\limsup _{k \rightarrow-\infty}\left|\varphi\left(0 ; k T, x_{0, k T}\right)-\mu(0)\right| \geq\left|a_{n}-\mu(0)\right|>0
$$

and thus $\mu$ would not be pullback attracting either. Overall, we see that (i) and (ii) both imply (iv).
Conversely, assume that $\Phi_{T}(a)-a>0>\Phi_{T}(b)-b$ for all $a<\mu(0)<b$ whenever $b-a<\varepsilon$. Pick $\delta>0$ so small that $\left.\bigcup_{0 \leq s \leq T} \Phi_{s}^{-1}(] \mu(s)-\delta, \mu(s)+\delta[) \subset\right] \mu(0)-\varepsilon, \mu(0)+\varepsilon[$, i.e., whenever $|x-\mu(s)|<\delta$ for some $s$ with $0 \leq s \leq T$ then also $\left|\Phi_{s}^{-1}(x)-\mu(0)\right|<\varepsilon$. Assume now that $\sup _{\sigma \in \mathbb{R}}\left|x_{0, \sigma}-\mu(\sigma)\right|<\delta$. Observing

$$
\begin{aligned}
\left|\varphi\left(\sigma+\tau ; \sigma, x_{0, \sigma}\right)-\mu(\sigma+\tau)\right| & =\left|\Phi_{s_{2}} \circ \Phi_{T}^{k} \circ \Phi_{s_{1}}^{-1}\left(x_{0, \sigma}\right)-\Phi_{s_{2}}(\mu(0))\right| \\
& \leq \sup _{0 \leq s \leq T}\left|\Phi_{s} \circ \Phi_{T}^{k} \circ \Phi_{s_{1}}^{-1}\left(x_{0, \sigma}\right)-\Phi_{s}(\mu(0))\right|
\end{aligned}
$$

with $s_{2}=\sigma+\tau-T\lfloor(\sigma+\tau) / T\rfloor, s_{1}=\sigma-T\lfloor\sigma / T\rfloor$ and $k=\lfloor(\sigma+\tau) / T\rfloor-\lfloor\sigma / T\rfloor$, and noting that $\left|\Phi_{s_{1}}^{-1}\left(x_{0, \sigma}\right)-\mu(0)\right|<\varepsilon$ for all $\sigma \in \mathbb{R}$, we deduce that $\left\|\varphi\left(\cdot+\tau ; \cdot, x_{0,}\right)-\mu(\cdot+\tau)\right\|_{\infty} \rightarrow 0$ as $\tau \rightarrow \infty$. In other words, $\mu$ is a uniform attractor.

Corollary 24. Assume (18) holds, and let $\mu: \mathbb{R} \rightarrow \mathbb{R}$ be a bounded solution of (3). Then $\mu$ is a uniform repellor if and only if $\mu$ is $T$-periodic and $\mu(0)$ is an isolated fixed point of $\Phi_{T}$ such that $\Phi_{T}(a)-a<0<\Phi_{T}(b)-b$ for all $a<\mu(0)<b$ with $b-a$ sufficiently small.

Remark 25. According to Lemma 22 and Theorem 23 an attractor $\mu$ cannot be subharmonic. It can, however, be superharmonic, i.e., the minimal period of $\mu$ can be smaller than $T$ and thus of the form $\frac{1}{q} T$ for some $q \in \mathbb{N}, q \geq 2$. For a simple example consider

$$
\dot{x}=2 \cos 2 t+(1+\cos t) \sin 2 t-(1+\cos t) x
$$

for which $f$ has minimal period $2 \pi$, yet the global uniform attractor $\mu: t \mapsto \sin 2 t$ is $\pi$-periodic.

For $T$-periodic functions $f$ it is natural to also study the averaged version of (3), i.e., the autonomous equation

$$
\dot{x}=\bar{f}(x) \quad \text { where } \bar{f}(x)=\frac{1}{T} \int_{0}^{T} f(t, x) \mathrm{d} t .
$$

Note that $\bar{f}(x)$ is a polynomial whenever $f(t, x)$ is polynomial in $x$. Sometimes information about solutions of (3) can be obtained from the averaged equation, see for instance [39] for an introduction to the extensive theory of averaging. In the present context the averaging approach leads to

Theorem 26. Assume $a_{0}, a_{1}, \ldots, a_{d}$ are continuous, $T$-periodic functions, and $\int_{0}^{T} a_{d}(t) \mathrm{d} t \neq 0$. Then, for every sufficiently small $\varepsilon>0$, the total number of uniform attractors and repellors of

$$
\begin{equation*}
\dot{x}=\varepsilon\left(a_{0}(t)+a_{1}(t) x+\cdots+a_{d}(t) x^{d}\right) \tag{19}
\end{equation*}
$$

is at most $d$.
Proof. According to Theorem 21 the statement is true for $d \leq 2$, even without any assumptions on $a_{d}$ and $\varepsilon$. We are therefore interested only in the case $d \geq 3$. For notational convenience we replace $\varepsilon$ in (19) by $\varepsilon^{d-1}$. Thus modified, and rescaled via $y=\varepsilon x$, (19) takes the form

$$
\begin{equation*}
\dot{y}=a_{d} y^{d}+\varepsilon a_{d-1} y^{d-1}+\cdots+\varepsilon^{d-1} a_{1} y+\varepsilon^{d} a_{0} . \tag{20}
\end{equation*}
$$

We are going to show that (20) has at most $d$ uniform attractors and repellors, provided that $\varepsilon>0$ is sufficiently small. Without loss of generality assume that $\int_{0}^{T} a_{d}(t) \mathrm{d} t>0$ as well as $a_{d}(0)>0$.

For $\varepsilon=0$ the solution of $(20)$ with $y(0)=z$ is given by

$$
\begin{equation*}
y: t \mapsto \frac{z}{\left(1-(d-1) A_{d}(t) z^{d-1}\right)^{\frac{1}{d-1}}}, \tag{21}
\end{equation*}
$$

where $A_{d}(t)=\int_{0}^{t} a_{d}(s) \mathrm{d} s, 0 \leq t \leq T$. This solution exists for all $0 \leq t \leq T$ and $\left.z \in\right]-C_{d}^{-}, C_{d}^{+}[$where, if $d$ is odd,

$$
0<C_{d}^{-}=C_{d}^{+}=\left((d-1) \max _{0 \leq t \leq T} A_{d}(t)\right)^{-\frac{1}{(d-1)}}<\infty
$$

whereas for even $d$ the value of $C_{d}^{+}$remains unchanged but

$$
0<C_{d}^{-}=\left(-(d-1) \min _{0 \leq t \leq T} A_{d}(t)\right)^{-\frac{1}{(d-1)}} \leq \infty
$$

(If $A_{d}(t) \geq 0$ for all $t$ then $C_{d}^{-}$is understood to equal $\infty$.) Correspondingly, the Poincaré map associated with (20) can be written in the form

$$
\begin{equation*}
\Phi_{T}(z)=\frac{z}{\left(1-(d-1) A_{d}(T) z^{d-1}\right)^{\frac{1}{d-1}}}+\varepsilon R(z, \varepsilon) \tag{22}
\end{equation*}
$$

where, for every compact set $K \subset]-C_{d}^{-}, C_{d}^{+}$[ and $\varepsilon$ sufficiently small, $R$ depends continuously on $(z, \varepsilon)$ and is in fact a (real-)analytic function of $z$. Moreover, uniformly on $K$,

$$
R(z, \varepsilon) \rightarrow z^{d-1} \int_{0}^{T} a_{d-1}(t)\left(1-(d-1) A_{d}(t) z^{d-1}\right)^{\frac{1}{d-1}} \mathrm{~d} t \quad \text { as } \varepsilon \rightarrow 0
$$

Similarly, integrating (20) in backward time, or inverting (22), yields

$$
\Phi_{T}^{-1}(z)=\frac{z}{\left(1+(d-1) A_{d}(T) z^{d-1}\right)^{\frac{1}{d-1}}}+\varepsilon S(z, \varepsilon),
$$

a map analytic on $]-\widetilde{C}_{d}^{-}, \widetilde{C}_{d}^{+}[$where, as before, for odd $d$,

$$
0<\widetilde{C}_{d}^{-}=\widetilde{C}_{d}^{+}=\left((d-1)\left(\max _{0 \leq t \leq T} A_{d}(t)-A_{d}(T)\right)\right)^{-\frac{1}{(d-1)}} \leq \infty,
$$

whereas for even $d$ the number $\widetilde{C}_{d}^{+}$remains unchanged, yet

$$
0<\widetilde{C}_{d}^{-}=\left((d-1)\left(A_{d}(T)-\min _{0 \leq t \leq T} A_{d}(t)\right)\right)^{-\frac{1}{(d-1)}}<\infty
$$

Note that, since $A_{d}(T)>0$, we have $\widetilde{C}_{d}^{+}>C_{d}^{+}$; also $\widetilde{C}_{d}^{-}>C_{d}^{-}$or $\widetilde{C}_{d}^{-}<C_{d}^{-}$depending on whether $d$ is odd or even.
It is easy to see that for every $t_{0} \in[0, T]$ with $a_{d}\left(t_{0}\right) \neq 0$ there exist positive numbers $D_{t_{0}}, \delta_{t_{0}}$ not depending on $\varepsilon$ such that, for any bounded solution $v$ of (20),

$$
|\nu(t)| \leq D_{t_{0}} \quad \forall t:\left|t-t_{0}\right|<\delta_{t_{0}} .
$$

Assume now that $v_{\varepsilon}$ is a $T$-periodic solution of (20). Since $a_{d}(0)>0$ we clearly have $\left|\nu_{\varepsilon}(0)\right| \leq D_{0}$ for all $\varepsilon>0$. As a key step in our analysis, we are going to show that actually

$$
\begin{equation*}
\lim _{\varepsilon \rightarrow 0} v_{\varepsilon}(0)=0 \tag{23}
\end{equation*}
$$

To this end, pick $\nu_{0}>C_{d}^{+}$and note that, according to (21), the solution of (20) with $\varepsilon=0$ and $y(0)=\nu_{0}$ becomes unbounded for some $t^{*}$ with $0<t^{*} \leq T$. By increasing $\nu_{0}$ slightly we may assume that $a_{d}\left(t^{*}\right) \neq 0$. Pick $\delta<\delta_{t^{*}}$ so small that $y\left(t^{*}-\delta\right)>D_{t^{*}}$. If, for some sequence $\left(\varepsilon_{n}\right)$ with $\varepsilon_{n} \rightarrow 0$, we had $v_{\varepsilon_{n}}(0) \rightarrow \nu_{0}$, that is, if $\lim \sup _{\varepsilon \rightarrow 0} \nu_{\varepsilon}(0) \geq \nu_{0}$, then, by the continuous dependence on $\varepsilon$ of the solutions of (20),

$$
v_{\varepsilon_{n}}\left(t^{*}-\delta\right) \rightarrow y\left(t^{*}-\delta\right)>D_{t^{*}} \quad \text { as } n \rightarrow \infty .
$$

Clearly this would contradict the fact that, for all $n$,

$$
\left|v_{\varepsilon_{n}}(t)\right| \leq D_{t^{*}} \quad \forall t:\left|t-t^{*}\right|<\delta_{t^{*}} .
$$

Hence $\lim \sup _{\varepsilon \rightarrow 0} \nu_{\varepsilon}(0)<\nu_{0}$, and, since $\nu_{0}>C_{d}^{+}$was arbitrary, we deduce $\lim \sup _{\varepsilon \rightarrow 0} \nu_{\varepsilon}(0) \leq C_{d}^{+}$. Completely similar reasoning, using the fact that (21) becomes unbounded in forward (if $d$ is odd) or backward time (if $d$ is even) whenever $y(0)<-\widetilde{C}_{d}^{-}$, shows that $\lim _{\inf }^{\varepsilon \rightarrow 0} 0 \nu_{\varepsilon}(0) \geq-\widetilde{C}_{d}^{-}$. To see that the inequalities in these relations are strict assume that $v_{\varepsilon_{n}}(0) \rightarrow C_{d}^{+}$. Then

$$
\nu_{\varepsilon_{n}}(0)=\Phi_{T}^{-1}\left(\nu_{\varepsilon_{n}}(0)\right) \rightarrow \frac{C_{d}^{+}}{\left(1+(d-1) A_{d}(T)\left(C_{d}^{+}\right)^{d-1}\right)^{\frac{1}{d-1}}}<C_{d}^{+}
$$

an obvious contradiction; for $\nu_{\varepsilon_{n}}(0) \rightarrow-\widetilde{C}_{d}^{-}$considering $\nu_{\varepsilon_{n}}(0)=\Phi_{T}^{-1}\left(\nu_{\varepsilon_{n}}(0)\right)$ if $d$ is odd, and $\nu_{\varepsilon_{n}}(0)=$ $\Phi_{T}\left(v_{\varepsilon_{n}}(0)\right)$ if $d$ is even, leads to a similar contradiction. We deduce from all this that

$$
-\widetilde{C}_{d}^{-}<\liminf _{\varepsilon \rightarrow 0} v_{\varepsilon}(0) \leq \limsup _{\varepsilon \rightarrow 0} v_{\varepsilon}(0)<C_{d}^{+} .
$$

Now the above argument can be iterated. Let $v_{\varepsilon_{n}}(0) \rightarrow a$ and assume first that $0 \leq a<C_{d}^{+}$. Then

$$
a=\lim _{n \rightarrow \infty} v_{\varepsilon_{n}}(0)=\lim _{n \rightarrow \infty} \Phi_{T}^{-1}\left(v_{\varepsilon_{n}}(0)\right)=\frac{a}{\left(1+(d-1) A_{d}(T) a^{d-1}\right)^{\frac{1}{d-1}}},
$$

and hence $a=0$; similarly, if $-\widetilde{C}_{d}^{-}<a \leq 0$ then $a=0$. Thus we have established (23).
To conclude the proof, let $v_{\varepsilon}^{(1)}, \ldots, \nu_{\varepsilon}^{(L)}$ be $L$ different uniform attractors or repellors of (20) and pick $C<$ $\min \left(\widetilde{C}_{d}^{-}, C_{d}^{+}\right)$. Then $\left|v_{\varepsilon}^{(i)}(0)\right|<C$ for all $i=1, \ldots, L$ and all sufficiently small $\varepsilon$. When considered a function of the complex variable $z, \Phi_{T}$ according to (22) is, for small $\varepsilon$, analytic on (an open set containing the closure of) the open disc $B_{C}=\{z:|z|<C\}$ and, uniformly on $B_{C}$,

$$
\Phi_{T}(z)-z \rightarrow \frac{z}{\left(1-(d-1) A_{d}(T) z^{d-1}\right)^{\frac{1}{d-1}}}-z=: G(z) \quad \text { as } \varepsilon \rightarrow 0 .
$$

The function $G$ is analytic on $B_{\min \left(\widetilde{C}_{d}^{-}, C_{d}^{+}\right)}$and does not vanish on the boundary of $B_{C}$. By Hurwitz's Theorem (see e.g. [37]) there exists $\varepsilon_{0}>0$ such that, for all $0<\varepsilon<\varepsilon_{0}$, the functions $\Phi_{T}-\mathrm{id}_{\mathbb{C}}$ and $G$ have the same number of
zeros in $B_{C}$, where all zeros are counted according to their multiplicity. Clearly, $G(z)=0$ implies $z=0$, and from

$$
G(z)=\frac{z}{\left(1-(d-1) A_{d}(T) z^{d-1}\right)^{\frac{1}{d-1}}}-z=A_{d}(T) z^{d}+\mathcal{O}\left(z^{2 d-1}\right),
$$

we see that $z=0$ is a $d$-fold zero of $G$. Consequently, for $\varepsilon<\varepsilon_{0}$, the Poincaré map $\Phi_{T}$ has exactly $d$ complex fixed points; as a function of the real argument $z, \Phi_{T}$ has at most $d$ fixed points. Hence $L \leq d$ and the proof is complete.

Remark 27. (i) The assumption $\int_{0}^{T} a_{d}(t) \mathrm{d} t \neq 0$ in Theorem 26 ensures that the averaged right-hand side in (19) has actual degree $d$. In this case, and if $\mu_{\varepsilon}$ is a uniform attractor or repellor of (19) such that $\varepsilon \mapsto \mu_{\varepsilon}(0)$ is continuous, one can show that, uniformly in $t$,

$$
\mu_{\varepsilon}(t) \rightarrow \mu_{0} \quad \text { as } \varepsilon \rightarrow 0
$$

where $\mu_{0}$ is an equilibrium of the averaged equation, that is, $\bar{p}\left(\mu_{0}\right)=0$ with

$$
\bar{p}(x)=\int_{0}^{T} a_{0}(t) \mathrm{d} t+x \int_{0}^{T} a_{1}(t) \mathrm{d} t+\cdots+x^{d} \int_{0}^{T} a_{d}(t) \mathrm{d} t
$$

An outline of the argument which extends [40, Thm. 3.1] is as follows: A lengthy yet elementary calculation yields a refined version of (22) for the representation of the Poincaré map $\Phi_{T}$ associated with (20), namely

$$
\begin{equation*}
\Phi_{T}(z)=\frac{z}{\left(1-(d-1) A_{d}(T) z^{d-1}\right)^{\frac{1}{d-1}}}+\sum_{i=1}^{d} \varepsilon^{i} R_{i}(z)+\varepsilon^{d+1} \widetilde{R}(z, \varepsilon), \tag{24}
\end{equation*}
$$

where

$$
R_{i}(z)=z^{d-i} \int_{0}^{T} a_{d-i}(t) \mathrm{d} t+\mathcal{O}\left(z^{2 d-2 i+1}\right) \quad(i=1, \ldots, d)
$$

and, as before, the remainder term $\widetilde{R}(z, \varepsilon)$ is analytic in $z$ and uniformly convergent as $\varepsilon \rightarrow 0$. In terms of the original coordinate $x$, representation (24) has the form

$$
\Phi_{T}(\varepsilon x)=\varepsilon x+\varepsilon^{d} \bar{p}(x)+\varepsilon^{d+1} \widetilde{R}(\varepsilon x, \varepsilon) .
$$

If $\mu_{\varepsilon}$ is a periodic solution of (19), again with $\varepsilon$ replaced by $\varepsilon^{d-1}$, then

$$
\varepsilon \mu_{\varepsilon}(0)=\Phi_{T}\left(\varepsilon \mu_{\varepsilon}(0)\right)=\varepsilon \mu_{\varepsilon}(0)+\varepsilon^{d} \bar{p}\left(\mu_{\varepsilon}(0)\right)+\varepsilon^{d+1} \widetilde{R}\left(\varepsilon \mu_{\varepsilon}(0), \varepsilon\right)
$$

and hence, for all $\varepsilon>0$,

$$
\bar{p}\left(\mu_{\varepsilon}(0)\right)+\varepsilon \widetilde{R}\left(\varepsilon \mu_{\varepsilon}(0), \varepsilon\right)=0 .
$$

Since the proof of Theorem 26 has shown that $\varepsilon \mu_{\varepsilon}(0) \rightarrow 0$ as $\varepsilon \rightarrow 0$, it follows that $\bar{p}\left(\mu_{\varepsilon}(0)\right) \rightarrow 0$ as well. Therefore, if $\varepsilon \mapsto \mu_{\varepsilon}$ is a continuous parametrisation then $\mu_{\varepsilon} \rightarrow \mu_{0}$ with $\bar{p}\left(\mu_{0}\right)=0$.
(ii) An explicit (upper) bound for $\varepsilon$ can be derived from an application of Rouché's Theorem, see [35] for a somewhat similar result.
(iii) It is intriguing to speculate whether Theorems 23 and 26 might have any analogues for almost periodic equations. In general an attractor of (3) can be much more complicated if $f=f(t, x)$ is merely almost periodic in $t$. However, it has been demonstrated in [41] that a form of uniformity (which, though different, does bear some similarity with the uniformity discussed here) greatly reduces the possible complexity of attractors.

We shall finally demonstrate that neither of the two assumptions in Theorem 26, namely smallness of $\varepsilon$ and preservation of the degree $d$ under averaging, can be discarded easily. To see the importance of the smallness of $\varepsilon$, recall from Theorem 21 that the size of $\varepsilon$ is irrelevant for the assertion in Theorem 26 as long as $d \leq 2$, and also if $d=3$ and $a_{3}$ does not change its sign. If, however, $a_{3}$ does change its sign, then Theorem 26 generally fails for larger $\varepsilon$, even if $\int_{0}^{T} a_{3}(t) \mathrm{d} t$ happens to be nonzero. This is the content of the following theorem which exploits an ingenious idea in [30].

Theorem 28. Let $a_{3}: \mathbb{R} \rightarrow \mathbb{R}$ be continuous and $T$-periodic, and assume $a_{3}$ does change its sign, i.e., $a_{3}(s) a_{3}(t)<0$ for some $s, t \in \mathbb{R}$. Then, given $N \in \mathbb{N}$, there exists a smooth, $T$-periodic function $a_{2}$ such that

$$
\begin{equation*}
\dot{x}=a_{2} x^{2}+a_{3} x^{3} \tag{25}
\end{equation*}
$$

## has $N$ uniform attractors.

Proof. We are going to construct a smooth, $T$-periodic function $a$ such that

$$
\begin{equation*}
\dot{y}=a y^{2}+\varepsilon^{2} a_{3} y^{3} \tag{26}
\end{equation*}
$$

has $N$ uniform attractors, provided that $\varepsilon>0$ is sufficiently small. This will prove the theorem because setting $a_{2}=a / \varepsilon$ and rescaling (26) via $x=\varepsilon y$ yields (25).

Given $a_{3}$ with the stated properties it remains to find $a$ such that, for small $\varepsilon$, (26) has $N$ uniform attractors. To this end, let $A(t)=\int_{0}^{t} a(s) \mathrm{d} s$ and observe that the solution of (26) for $\varepsilon=0$ and $y(0)=z$ is given by

$$
\varphi(t ; 0, z)=\frac{z}{1-z A(t)}
$$

We will choose $A \neq 0$ such that $A(0)=A(T)=0$. Thus every solution of (26) for $\varepsilon=0$ is $T$-periodic provided that $|z|<\left(\max _{0 \leq t \leq T}|A(t)|\right)^{-1}=: \gamma$. The Poincaré map associated with (26) can be written in the form

$$
\begin{equation*}
\Phi_{T}(z)=z+\varepsilon^{2} R(z)+\varepsilon^{3} S(z, \varepsilon) \tag{27}
\end{equation*}
$$

where $R(z)=z^{3} Q_{A}(z)$ and

$$
Q_{A}(z)=\int_{0}^{T} \frac{a_{3}(t)}{1-z A(t)} \mathrm{d} t
$$

and $S$ depends smoothly on $z$ and $\varepsilon$. Assume that $z_{0} \neq 0$ is a simple zero of $R$, i.e., $R\left(z_{0}\right)=0$ and $R^{\prime}\left(z_{0}\right) \neq 0$. Then, for every $\varepsilon>0$ sufficiently small, there exists $z_{\varepsilon}$ such that $R\left(z_{\varepsilon}\right)+\varepsilon S\left(z_{\varepsilon}, \varepsilon\right)=0$ and hence $\Phi_{T}\left(z_{\varepsilon}\right)=z_{\varepsilon}$. Moreover,

$$
\Phi_{T}^{\prime}\left(z_{\varepsilon}\right)=1+\varepsilon^{2} R^{\prime}\left(z_{\varepsilon}\right)+\varepsilon^{3} \frac{\partial}{\partial z} S\left(z_{\varepsilon}, \varepsilon\right) \neq 1
$$

so that $t \mapsto \varphi\left(t ; 0, z_{\varepsilon}\right)$ is, by Theorem 23, a uniform attractor or repellor of (26). Note that $z_{0}$ is a zero of $Q_{A}$ also, and $R^{\prime}\left(z_{0}\right)=z_{0}^{3} Q_{A}^{\prime}\left(z_{0}\right)$. The proof will therefore be complete once we can choose $A$ in such a way that $Q_{A}$ has $N$ distinct zeros $\zeta_{1}, \ldots, \zeta_{N}$ with $Q_{A}^{\prime}\left(\zeta_{i}\right)<0$ and $0<\zeta_{i}<\gamma$ for all $i=1, \ldots, N$. To this end, and denoting the indicator function of an arbitrary set $M \subset \mathbb{R}$ by $\mathbf{1}_{M}$, we first use the (non-smooth) ansatz

$$
\begin{equation*}
A(t)=\sum_{i=1}^{2 N} \alpha_{i} \mathbf{1}_{I_{i}}(t) \quad(0 \leq t \leq T) \tag{28}
\end{equation*}
$$

where the positive numbers $\alpha_{i}$ and the compact intervals $\left.I_{i} \subset\right] 0, T$ [ will be chosen inductively below. In a final step we will afterwards approximate $A$ from below by a $C^{\infty}$ function $\widetilde{A}$, and $a=\frac{\mathrm{d}}{\mathrm{d} t} \widetilde{A}$ will have all the properties required.

Assume for the time being that $\int_{0}^{T} a_{3}(t) \mathrm{d} t>0$. Pick $2 N$ different points $0<t_{1}, \ldots, t_{2 N}<T$ such that

$$
\begin{equation*}
(-1)^{i} a_{3}\left(t_{i}\right)>0 \quad \forall i=1, \ldots, 2 N . \tag{29}
\end{equation*}
$$

Define $t_{0}=0$ and $t_{2 N+1}=T$ and let $\delta=\frac{1}{2} \min \left\{\left|t_{j}-t_{k}\right|: j, k=0, \ldots, 2 N+1 ; j \neq k\right\}$; also define functions $Q^{(1)}, \ldots, Q^{(2 N)}$ as

$$
Q^{(i)}(z)=\int_{0}^{T} a_{3}(t) \mathrm{d} t+\sum_{j=1}^{i} \frac{\alpha_{j} z}{1-\alpha_{j} z} \int_{I_{j}} a_{3}(t) \mathrm{d} t \quad(i=1, \ldots, 2 N),
$$

so that in particular $Q^{(2 N)}=Q_{A}$ with $A$ according to (28). Set $\alpha_{1}=1$, and let $I_{1}=\left[t_{1}-\frac{1}{2} \delta_{1}, t_{1}+\frac{1}{2} \delta_{1}\right]$ with $\delta_{1}<\delta$ so small that $\int_{I_{1}} a_{3}(t) \mathrm{d} t<0$. There exists a unique number $\zeta_{1}^{(1)}$ with $0<\zeta_{1}^{(1)}<1$ such that $Q^{(1)}\left(\zeta_{1}^{(1)}\right)=0$ yet $\frac{\mathrm{d}}{\mathrm{d} z} Q^{(1)}\left(\zeta_{1}^{(1)}\right) \neq 0$ (see Fig. 4), i.e., $\zeta_{1}^{(1)}$ is a simple root of $Q^{(1)}$. Next let $\alpha_{2}=3 /\left(\zeta_{1}^{(1)}+2\right.$ )

Fig. 4. Visualising the first steps in the proof of Theorem 28.
and $I_{2}=\left[t_{2}-\frac{1}{2} \delta_{2}, t_{2}+\frac{1}{2} \delta_{2}\right]$ where $\delta_{2}<\delta$ is chosen sufficiently small to ensure that $\int_{I_{2}} a_{3}(t) \mathrm{d} t>0$ as well as $Q^{(2)}\left(\frac{2}{3} \zeta_{1}^{(1)}+\frac{1}{3}\right)<0$. Consequently, there exist two numbers $\zeta_{1}^{(2)}, \zeta_{2}^{(2)}$ with $0<\zeta_{1}^{(2)}<\frac{2}{3} \zeta_{1}^{(1)}+\frac{1}{3}<\zeta_{2}^{(2)}<\alpha_{2}^{-1}$ such that $Q^{(2)}\left(\zeta_{1}^{(2)}\right)=Q^{(2)}\left(\zeta_{2}^{(2)}\right)=0$. Obviously, $Q^{(2)}$ has no other roots apart from $\zeta_{1}^{(2)}, \zeta_{2}^{(2)}$, and the latter are simple. Assume that $1=\alpha_{1}<\alpha_{2}<\cdots<\alpha_{i}$ as well as $\delta_{1}, \ldots, \delta_{i}<\delta$ have been chosen inductively such that $Q^{(i)}$ has $i$ simple roots $0<\zeta_{1}^{(i)}<\cdots<\zeta_{i}^{(i)}<\alpha_{i}^{-1}$. Let $\alpha_{i+1}=3 /\left(\zeta_{i}^{(i)}+2 \alpha_{i}^{-1}\right)$ and $I_{i+1}=\left[t_{i+1}-\frac{1}{2} \delta_{i+1}, t_{i+1}+\frac{1}{2} \delta_{i+1}\right]$. The number $\delta_{i+1}<\delta$ is chosen so small that $(-1)^{i+1} \int_{I_{i+1}} a_{3}(t) \mathrm{d} t>0$ and $(-1)^{i} Q^{(i+1)}\left(\frac{2}{3} \zeta_{i}^{(i)}+\frac{1}{3} \alpha_{i+1}^{-1}\right)>0$ but also

$$
(-1)^{j} Q^{(i+1)}\left(\frac{1}{2} \zeta_{j}^{(i)}+\frac{1}{2} \zeta_{j+1}^{(i)}\right)>0 \quad \forall j=1, \ldots, i-1
$$

The function $Q^{(i+1)}$ has $i+1$ zeros $\zeta_{1}^{(i+1)}, \ldots, \zeta_{i+1}^{(i+1)}$ with

$$
0<\zeta_{1}^{(i+1)}<\frac{1}{2} \zeta_{1}^{(i)}+\frac{1}{2} \zeta_{2}^{(i)}<\zeta_{2}^{(i+1)}<\cdots<\frac{2}{3} \zeta_{i}^{(i)}+\frac{1}{3} \alpha_{i+1}^{-1}<\zeta_{i+1}^{(i+1)}<\alpha_{i+1}^{-1}
$$

Since $Q^{(i+1)}$ is the sum of $i+1$ rational functions of degree one and therefore can have at most $i+1$ zeros, all the numbers $\zeta_{j}^{(i+1)}$ are simple zeros, in fact,

$$
(-1)^{j} \frac{\mathrm{~d}}{\mathrm{~d} z} Q^{(i+1)}\left(\zeta_{j}^{(i+1)}\right)>0 \quad \forall j=1, \ldots, i+1
$$

By carrying out $2 N$ steps of the above procedure (see also Fig. 4) we obtain a function $Q=Q^{(2 N)}$ having $N$ different $\operatorname{zeros} \zeta_{1}^{(2 N)}, \zeta_{3}^{(2 N)}, \ldots, \zeta_{2 N-1}^{(2 N)}$ with $Q^{\prime}\left(\zeta_{2 i-1}^{(2 N)}\right)<0$ for all $i=1, \ldots, N$. Clearly

$$
\zeta_{i}^{(2 N)} \leq \zeta_{2 N}^{(2 N)}<\alpha_{2 N}^{-1}=\gamma \quad \forall i=1, \ldots, 2 N
$$

hence the usage of (27) is justified. Finally, to produce a smooth function $a$, let $A_{n}$ be an increasing sequence of smooth, non-negative functions such that for all $0 \leq t \leq T, 0 \leq A_{n}(t) \leq A(t)$ for all $n \in \mathbb{N}$ and $\lim _{n \rightarrow \infty} A_{n}(t)=A(t)$. Pick $C$ between $\zeta_{2 N}^{(2 N)}$ and $\gamma$. By dominated convergence, $\lim _{n \rightarrow \infty} Q_{A_{n}}(z)=Q_{A}(z)$ uniformly for $0 \leq z \leq C$. For sufficiently large $n$ therefore $Q_{A_{n}}$ has $N$ different $\underset{\sim}{\operatorname{A}} \underset{\sim}{\sim}$ ple zeros with negative slope as well. Extending $\bar{A}_{n}$ to a smooth $T$-periodic function $\widetilde{A}: \mathbb{R} \rightarrow \mathbb{R}$ and setting $a=\frac{\mathrm{d}}{\mathrm{d} t} \widetilde{A}$ completes the proof for the case $\int_{0}^{T} a_{3}(t) \mathrm{d} t>0$.

If $\int_{0}^{T} a_{3}(t) \mathrm{d} t<0$ then completely analogous reasoning applies with all signs inverted, e.g., (29) has to be replaced by

$$
(-1)^{i} a_{3}\left(t_{i}\right)<0 \quad \forall i=1, \ldots, 2 N \text { etc. }
$$

Finally, if $\int_{0}^{T} a_{3}(t) \mathrm{d} t=0$ then $Q^{(1)}$ will not have a zero except for $z=0$. Therefore, $2 N+1$ rather than $2 N$ points $t_{i}$ have to be chosen; apart from this modification the same procedure as above applies. Overall, the proof is complete.

As a demonstration that Theorem 21 cannot be extended to any $d$ larger than three, even with a definiteness assumption for $a_{d}$, we provide

Corollary 29. Let $d \geq 4$ be a natural number, and assume $a_{d}: \mathbb{R} \rightarrow \mathbb{R}$ is continuous, $T$-periodic and either nonnegative or non-positive. Then, given $N \in \mathbb{N}$, there exist smooth, $T$-periodic functions $a_{2}, a_{3}$ such that

$$
\begin{equation*}
\dot{x}=a_{2} x^{2}+a_{3} x^{3}+a_{d} x^{d} \tag{30}
\end{equation*}
$$

has $N$ uniform attractors.
Proof. Up to and including terms of order $\varepsilon^{2}$, the Poincaré map $\Phi_{T}$ associated with

$$
\begin{equation*}
\dot{y}=a y^{2}+\varepsilon^{2} a_{3} y^{3}+\varepsilon^{d-1} a_{d} y^{d} \tag{31}
\end{equation*}
$$

is identical with the one in the previous proof, that is, (27) holds with only the remainder term $S$ modified. Thus, taking as $a_{3}$ any smooth, $T$-periodic function which changes its sign and subsequently constructing $a$ as in the proof of Theorem 28, we conclude that (31) has $N$ uniform attractors whenever $\varepsilon>0$ is sufficiently small. Setting $a_{2}=a / \varepsilon$ and rescaling (31) via $x=\varepsilon y$ yields (30).

Our final result highlights the role of the non-degeneracy condition $\int_{0}^{T} a_{d}(t) \mathrm{d} t \neq 0$ in Theorem 26 by showing that the latter generally fails if this condition is not met.

Corollary 30. Let $d \geq 3$ be a natural number and $a_{d} \neq 0$ a continuous, $T$-periodic function with $\int_{0}^{T} a_{d}(t) \mathrm{d} t=0$. Then, given $N \in \mathbb{N}$, there exists a smooth $T$-periodic function $a_{2}$ such that, for all sufficiently small $\varepsilon>0$,

$$
\begin{equation*}
\dot{x}=\varepsilon\left(a_{2} x^{2}+a_{\mathrm{d}} x^{d}\right) \tag{32}
\end{equation*}
$$

has $N$ uniform attractors.
Proof. The argument is quite similar to the one proving Theorem 28. Clearly, the assertion remains unchanged if, for notational convenience, $\varepsilon$ is replaced by $\varepsilon^{d-1}$ in (32). Thus modified, and rescaled via $x=y / \varepsilon$, (32) takes the form

$$
\begin{equation*}
\dot{y}=\varepsilon^{d-2} a_{2} y^{2}+a_{d} y^{d} . \tag{33}
\end{equation*}
$$

The proof will therefore be complete once we demonstrate how to find $a_{2}$ not depending on $\varepsilon$ such that (33) has $N$ uniform attractors or repellors for all sufficiently small $\varepsilon>0$.

Let $A_{d}=\int_{0}^{t} a_{d}(s) \mathrm{d} s$ and note that $A_{d}(0)=A_{d}(T)=0$. Similarly to (27) the Poincaré map $\Phi_{T}$ associated with (33) can be written as

$$
\begin{equation*}
\Phi_{T}(z)=z+\varepsilon^{d-2} R(z)+\varepsilon^{d-1} S(z, \varepsilon) \tag{34}
\end{equation*}
$$

with $R(z)=z^{2} Q_{a_{2}}(z)$ and

$$
Q_{a_{2}}(z)=\int_{0}^{T} a_{2}(t)\left(1-(d-1) A_{d}(t) z^{d-1}\right)^{\frac{d-2}{d-1}} \mathrm{~d} t
$$

provided that $|z|<C_{d}$, where

$$
C_{d}=\left((d-1) \max _{0 \leq t \leq T}\left|A_{d}(t)\right|\right)^{-\frac{1}{d-1}}>0
$$

As before, it only remains to choose $a_{2}$ in such a way that $Q_{a_{2}}$ has $N$ simple zeros within the interval $] 0, C_{d}[$.
Obviously, $Q_{a_{2}}$ depends linearly upon $a_{2}$, and, for $|z|<C_{d}$,

$$
Q_{a_{2}}(z)=\sum_{k=0}^{\infty}\left(\frac{d-2}{d-1}\right)(1-d)^{k} z^{k(d-1)} \int_{0}^{T} a_{2}(t) A_{d}^{k}(t) \mathrm{d} t .
$$

Thus, if $a_{2}$ is orthogonal to $\mathbf{1}\left(=A_{d}^{0}\right), A_{d}, \ldots, A_{d}^{i-1}$ yet not orthogonal to $A_{d}^{i}$ then the leading term of $Q_{a_{2}}(z)$ will be of the order $z^{i(d-1)}$. More formally, choose $N$ smooth, $T$-periodic functions $a_{2}^{(i)}, i=1, \ldots, N$ such that, for all $i$,

$$
\int_{0}^{T} a_{2}^{(i)}(t) \mathrm{d} t=\int_{0}^{T} a_{2}^{(i)}(t) A_{d}(t) \mathrm{d} t=\cdots=\int_{0}^{T} a_{2}^{(i)}(t) A_{d}^{i-1}(t) \mathrm{d} t=0 \quad \text { yet } \int_{0}^{T} a_{2}^{(i)}(t) A_{d}^{i}(t) \mathrm{d} t \neq 0
$$

(Such a choice is possible because $A_{d}$ is continuous but not constant.). With this,

$$
Q_{a_{2}^{(i)}}(z)=q_{i} z^{i(d-1)}+\mathcal{O}\left(z^{(i+1)(d-1)}\right) \quad(i=1, \ldots, N)
$$

with constants $q_{i} \neq 0$. From (a slightly generalised version of) [30, Lem. 3.1] it follows that there exist positive numbers $\gamma_{1}, \ldots, \gamma_{N}$ such that with

$$
a_{2}=\gamma_{N} a_{2}^{(N)}-\gamma_{N-1} a_{2}^{(N-1)}+\cdots+(-1)^{N-1} \gamma_{1} a_{2}^{(1)}
$$

the function $Q_{a_{2}}$ has $N$ simple zeros in $] 0, C_{d}[$.

## 4. Concluding remarks

The success of classical bifurcation theory for autonomous differential equations $\dot{x}=F(x ; \lambda)$ which depend on a parameter $\lambda$ is due to several facts which, albeit obvious, have to be reconsidered carefully when a nonautonomous bifurcation theory is to be developed:
(i) Many relevant models in applied sciences are indeed of the form $\dot{x}=F(x ; \lambda)$;
(ii) Potential bifurcating objects like equilibria and periodic orbits are characterised algebraically as zeros of $F$ and a Poincaré map, respectively;
(iii) Usually, there are not too many bifurcating objects, and the generic ones can to some extent be classified [2];
(iv) Asymptotic stability of equilibria and periodic orbits can be determined through linear algebra by means of, respectively, the linearisation of $F$ and a Poincaré map;
(v) The transient behaviour of solutions is related to their asymptotic behaviour; more precisely, the long-term dynamics of an attractive equilibrium or periodic orbit can be approximated arbitrarily well by the transient behaviour on longer and longer time intervals. In particular, finite time numerics can be used to approximate asymptotic behaviour.

The results in this article show that in many respects the nonautonomous situation remains fundamentally different from the autonomous one, and the simple facts provided here allow for a clear understanding as to why this is so. Concretely, when reconsidering the above list in an nonautonomous setting one is lead naturally to a variety of fundamental questions which we feel are largely open at present.
(i) $)_{t}$ What are the characteristics of a prototypical nonautonomous model $\dot{x}=f(t, x ; \lambda)$ ? How can one choose the appropriate time dependence for $f$ ? So far, we have studied nonautonomous attraction and repulsion only in its simplest uniform version for scalar equations. Already an astonishing dynamical complexity emerges which is in a sense due to the lack of better knowledge about how precisely $f$ depends on $t$ or, more positively put, the amazing "degree of freedom" which comes with time-varying vector fields. For example, our analysis of periodic equations does not incorporate the rate $\frac{\partial}{\partial t} f$ at which $f$ is changing in time. On the other hand, this rate is known to play a prominent role for instance in explicit conditions ensuring asymptotic stability (albeit in a slightly different context, see [11]). We feel it necessary to push for the development, driven by applications, of a methodology of nonautonomous modelling.
(ii) $)_{t}$ Uniformly attracting or repelling solutions cannot be detected algebraically, e.g. by looking for zeros of $f$. Rather, the asymptotic behaviour and the spatial structure of $(1)_{t}$ tend to be interwoven in an intricate manner. Theorems 17 and 26 may serve as simple but perhaps prototypical examples. In fact, we expect that most questions regarding uniform attractors will touch upon a delicate balance between temporal and spatial complexity (see also [28]). Versatile, effective tools for analysing this balance have yet to be developed.
(iii) $_{t}$ In view of Theorems 26 and 28 it appears doubtful whether the clear-cut situation for autonomous equations (i.e., few, classifiable bifurcation scenarios) does have an analogue in the nonautonomous setting. If so, a satisfactory treatment of the classification problem is desirable; if not, a bewildering zoo of bifurcation phenomena is likely to await exploration.
(iv) ${ }_{t}$ Attraction or repulsion of a solution can in general not be determined directly from the coefficients of the linearisation (see e.g. the instructive example in [28]). To comprehensively cover uniform attractors and repellors the existing asymptotic methods for nonautonomous equations will need substantial refinement.
$(\mathrm{v})_{t}$ What is the transient behaviour of a uniformly attracting or repelling solution, in particular, how repelling can a uniformly attracting solution be on an arbitrary bounded interval in time? We argue that this question is relevant not only for obvious practical reasons (as for instance no physical observation can cover an infinite interval in time) but also for mathematical reasons. In view of the enormous freedom introduced via an explicit yet unspecified time dependence in $(1)_{t}$ it is plausible that quite generally asymptotic concepts are of limited use and finite time concepts may step in.

In the context of $(\mathrm{v})_{t}$ we mention in closing a recent approach [5,12] that avoids any assumptions on the time dependence of $f$ and that instead studies the transient behaviour of (1) $)_{t}$ on intervals of finite time by exploiting all available (numerical) information. A solution $x$ of (1) $)_{t}$ on a finite time interval $[a, b]$ is attracting if $S(t):=$ $\frac{\partial}{\partial x} f(t, x(t))$, or more generally the symmetric matrix $S(t):=\frac{1}{2}\left[\frac{\partial}{\partial x} f(t, x(t))+\frac{\partial}{\partial x} f(t, x(t))^{T}\right]$ if $x \in \mathbb{R}^{n}, n \geq 2$, is negative (definite) for all $t \in[a, b]$. As a consequence, if $x$ is attracting then all solutions which are close to $x$ have a decreasing distance from $x$ on $[a, b]$; analogously, $x$ is repelling if $S(t)$ is positive (definite) for all $t \in[a, b]$. It is easy to see that the polynomial equation (16) with arbitrary time dependence on $[a, b]$ has at most $d$ connected components in $[a, b] \times \mathbb{R}$ such that each component consists entirely of attracting or repelling solutions. Observations like these suggest that finite time concepts may indeed complement asymptotic concepts and may thus contribute towards a better understanding of nonautonomous differential equations.
